Abstract
We compared the effect of recombinant human erythropoietin (rhEPO) administration by continuous s.c. infusion (CSI) with that of a weekly bolus s.c. injection (SBI) in five malnourished predialysis anemic patients with diabetic nephropathy. rhEPO was either continuously infused at a flow rate of 6000 IU per week (36 IU/h) (CSI group) or injected s.c. at a dose of 6000 IU once a week (SBI group) for 4 weeks, in a cross-over comparative study with a washout period of 4 weeks. Mean ± s.d. plasma EPO levels increased from a basal value of 18.0 ± 4.9 mIU/ml to a steady state value of 70.5 ± 38.9 mIU/ml 2 weeks after the start of CSI of rhEPO (P < 0.05). Increases in reticulocyte count above the basal value were greater in the CSI group than the SBI group at 3 weeks after the start of treatment (0.94 ± 0.35% vs −0.03 ± 0.46%, P < 0.05). Increases in Hb concentration above the basal value were much greater in the CSI group than the SBI group at 4 weeks after the start of treatment (2.56 ± 0.77 g/dl vs 0.28 ± 0.62 g/dl, P < 0.05). These findings suggest that rhEPO administration by CSI is more effective than by SBI for improving anemia in malnourished predialysis patients with diabetic nephropathy.

Introduction
Erythropoietin (EPO) production is induced by hypoxic stimuli and modulated by various hormones, nutritional factors and cytokines (1). Chronic renal failure (CRF) is accompanied by anemia in which serum EPO levels are low relative to blood hemoglobin (Hb) concentrations (2–4). CRF patients with diabetic nephropathy are often malnourished and accompanied by a number of metabolic abnormalities, water retention and diabetic vascular complications (5).

Recombinant human (rh)EPO administration is useful for improving not only anemia but also the quality of life in both dialysis and predialysis patients (6–9). rhEPO therapy has been delivered using a number of different dosages and administration methods in anemic patients with CRF during the predialysis period (10–12). However, malnourished patients with diabetic nephropathy often show a poor response to EPO administration.

In the present study, we compared the effect of continuous s.c. infusion (CSI) of rhEPO with that of s.c. bolus injection (SBI) in malnourished predialysis anemic patients with diabetic nephropathy.

Materials and methods
Patients
Five patients with diabetic nephropathy in the predialysis period were studied; their clinical characteristics are shown in Table 1. All patients were diagnosed as having non-insulin-dependent diabetes mellitus with diabetic nephropathy. The mean ± s.d. age was 69.4 ± 9.04 years (range 58–82). Body mass index (BMI), serum albumin and plasma insulin-like growth factor-I (IGF-I) levels were low in all the patients, suggesting undernourishment. Blood pressure and plasma glucose levels were well controlled during the study by diet alone (case 3) or in combination with insulin therapy (cases 1, 2, 4 and 5), although case 3 had been treated with insulin before good control had been gained by diet alone after renal function was impaired.

Study protocol
All patients were admitted to our hospital during the experimental period. Their diet was restricted to a total calorie intake of 30 kcal/kg of ideal body weight, protein...
of 1.0 g/kg of ideal body weight and salt of 5 g/day. Sodium ferrous citrate administration (100 mg/day, per os) was started in all the patients 2 months before the experimental period. The patients were divided into two groups at random, and rhEPO was given as either CSI or SBI for 4 weeks, alternately as a cross-over study with an interval of 4 weeks.

In the CSI group, rhEPO (Epoetin beta; Chugai Pharmaceutical Co., Tokyo, Japan) was infused s.c. into the abdomen for 4 weeks at a flow rate of 6000 IU/4 ml per week (36 IU/0.24 ml per h) using a portable infusion pump (SP-3HQ; Nipro Co., Osaka, Japan). In the SBI group, rhEPO 6000 IU was administered s.c. once a week at 0900 h into the upper arm. The cross-over comparative study of two protocols was randomly performed for the same patient with a washout period of 4 weeks. Both subjective and objective symptoms were evaluated every day. Blood pressure and body weight were measured every week. Blood samples were obtained in the morning after an overnight fasting every week for 4 weeks before and after the start of each rhEPO administration. Plasma samples were stored at −20 °C until assayed. Storage 24 h urine samples (0900 h to 0900 h) were obtained every week for 4 weeks after the start of each rhEPO administration. Blood Hb, reticulocyte count, serum and urine creatinine, serum albumin, blood urea nitrogen (BUN) and plasma EPO levels were measured every week. Serum iron, total iron-binding capacity (TIBC) and ferritin levels were measured every 2 weeks. Plasma EPO levels were determined by a specific RIA (Ricombigen EPO RIA Kit, Pharmacia Diagnostics, Uppsala, Sweden) as described previously (2). Informed consent was obtained from all patients.

**Statistical analysis**

Statistical analysis of the data was performed by one-way ANOVA in combination with Student’s t-test. P < 0.05 was considered significant.

**Results**

Serum creatinine and BUN levels were markedly elevated above normal whereas blood Hb, serum albumin, iron and TIBC levels were decreased in all subjects (Table 2). These patients also had decreased plasma IGF-I concentration and BMI, indicating malnutrition, although plasma glucose and HbA1c were well controlled. There were no statistical differences in these variables between the CSI group and the SBI group. No differences in plasma EPO levels were observed between the two groups before the treatment. Mean ± s.d. plasma EPO levels had increased from the basal value of 18.0 ± 4.9 mIU/ml to 62.5 ± 33.4 mIU/ml 1 week after the start of CSI of rhEPO (Fig. 1). Steady state plasma EPO levels were obtained during the next 3 weeks (70.5 ± 38.9, 72.1 ± 39.1 and 71.1 ± 37.4 mIU/ml at 2, 3 and 4 weeks respectively). In the SBI group, plasma EPO levels rapidly increased from the baseline of 22.1 ± 6.7 mIU/ml to above 235 mIU/ml at 12 h after the injection of rhEPO and then returned to the basal level within 3 days.

Increases in reticulocyte count were 0.74 ± 0.57 and 0.94 ± 0.35% at 1 and 3 weeks respectively in the CSI group, whereas there was no significant increase in the number of reticulocytes in the SBI group. Increases in reticulocyte count above the basal value were greater in the CSI group than the SBI group at 3 weeks after the start of treatment (0.94 ± 0.04% vs. 0.35% ± 0.35%, P < 0.05) (Fig. 2, upper panel). Hb concentration had increased by 0.96 ± 0.86, 1.10 ± 0.69 and 2.56 ± 0.77 g/dl at 2, 3 and 4 weeks respectively after the start of treatment.

**Table 2** Laboratory data for patients who received a continuous subcutaneous infusion of erythropoietin (CSI group) and those who received a subcutaneous bolus injection (SBI group). Values are mean ± S.D.

BUN, blood urea nitrogen.
of rhEPO treatment in the CSI group (Fig. 2, lower panel). On the other hand, in the SBI group, Hb concentration had only increased at 3 weeks, by 0.43 ± 0.48 g/dl. The increase in Hb concentration above the basal value at 4 weeks was higher in the CSI group than in the SBI group (P < 0.05).

Serum iron levels were slightly but not significantly decreased at 2 weeks in both groups. Serum TIBC, ferritin, creatinine and BUN levels were not changed in either group and neither was blood pressure or body weight.

Discussion

EPO is mainly secreted from the perivascular endothelial cells or fibroblasts in the kidney into the circulation (13). The synthesis of EPO is stimulated by hypoxia in the circulation (14). In patients with CRF, however, EPO secretion is relatively reduced compared with blood Hb concentrations (2). Furthermore, in patients with CRF due to diabetic nephropathy, anemia is also affected by metabolic disorders. EPO treatment is often ineffective for diabetic nephropathy (15, 16), but the precise reason for this blunted effect is not clear.

rhEPO treatment has been reported to be useful for improving anemia in predialysis patients with CRF (11, 12) without progression to renal failure (17, 18). Accumulating evidence suggests that SBI of rhEPO is more effective than i.v. administration, as SBI achieves the same effect at lower doses, although there have been some conflicting results (10, 19).

We first compared the effect of rhEPO administration by two different routes, CSI and SBI, in predialysis anemic patients with diabetic nephropathy. Plasma EPO levels were maintained by CSI within the upper normal limit in these subjects, whereas they superphysiologically increased but rapidly returned to basal values in the SBI group when the same total dose of rhEPO was given. Blood Hb concentration and reticulocyte count were more effectively improved by CSI than by SBI. These findings are in line with the report of Pavlovic-Kentera et al. (20) that a modest increase in serum EPO (30–60 mIU/ml) was sufficient to correct anemia in hemodialysed patients.

We conclude therefore that CSI of rhEPO is more useful than SBI for improving anemia in malnourished predialysis anemic patients with diabetic nephropathy.
