Abstract

Adrenomedullin (AM) is a novel vasorelaxant peptide, isolated from human pheochromocytoma. Although AM may be involved in the regulation of the cardiovascular system, a number of other mechanisms are also involved. The present study was undertaken to confirm the presence of AM in human maternal circulation and in placental function during pregnancy. Immunoreactive (ir) AM concentrations in maternal plasma were 3.4 ± 0.7 fmol/ml (mean ± S.E.M.) in the first trimester, 3.3 ± 1.1 fmol/ml in the second trimester, 7.3 ± 2.8 fmol/ml in the third trimester, 4.1 ± 1.9 fmol/ml in early puerperium and 3.0 ± 0.4 fmol/ml in non-pregnant periods; the concentration in the third trimester was significantly greater than those in other periods. Plasma concentrations of estradiol (E2), progesterone, human placental lactogen (hPL) and human chorionic gonadotropin (hCG) were also measured, using RIA kits. Significant correlations have been demonstrated between the concentrations of irAM and those of E2, progesterone and hPL. We therefore examined the expression of AM within the placental tissues using immunohistochemistry and northern blot analysis in order to demonstrate a correlation between the presence of AM in the placenta and maternal plasma. Using immunohistochemistry, we detected AM in the amnion at term and the expression of AM mRNA in human placental tissues using cloned human (h) AM complementary DNA as a probe. This study demonstrates the immunoreactivity of human hAM in maternal plasma during pregnancy, and suggests that hAM in maternal plasma is generated partly from placental tissue.

European Journal of Endocrinology 142 683–687

Introduction

Adrenomedullin (AM) is a novel vasorelaxing hypotensive peptide isolated from human pheochromocytoma (1). Human AM (hAM) consists of 52 amino acid residues with a ring structure stabilized by a disulfide bridge and C-terminal amide. It has partial structural homology with calcitonin gene-related peptide (CGRP) and amylin. It is reported that AM has a marked and long-lasting hypotensive effect in rats in vivo (2). Therefore, it appears likely that AM regulates blood flow.

It has been shown that immunoreactive (ir) AM is present in various human tissues, including adrenal glands, kidney and heart: the adrenal medulla and pheochromocytoma contain extremely high concentrations (3). irhAM has been shown to circulate in human plasma (4, 5), suggesting its role as a vasodilatory hormone, and circulating irhAM is known to be secreted mainly from vascular cells (2). Some papers have reported that the concentration of AM is increased in pregnancy (6, 7), similarly to other vasodilatory substances such as prostacyclin and prostaglandin E2 (8, 9). Montuenga et al. (10) reported that placental tissues of mouse and rat express high levels of AM and AM receptor. Furthermore, irAM and/or AM mRNA has been detected in human feto–placental tissues in the second trimester (11) and at term (12). These findings suggest that the circulation of AM during pregnancy may be related, not only to systemic hemodynamic changes, but also to feto–placental function, in addition to vascular function.

The present study was undertaken to measure the concentrations of hAM and placenta-related hormones in the maternal plasma during pregnancy, and to investigate whether normal placental tissues express the AM gene and/or exhibit AM immunostaining, suggesting the possible involvement of AM in feto-placental functions during pregnancy.
Materials and methods

Materials

For measurement of hAM, blood samples were obtained from 27 pregnant women (nine in the first trimester (6–12 weeks of gestation), nine in the second trimester (13–28 weeks of gestation), nine in the third trimester (29–40 weeks of gestation)), from nine women in early puerperium, and from six women in the luteal phase of no pregnancy. For immunohistochemical and northern blot analyses, placenta, villi and decidua were obtained immediately after normal vaginal delivery at term and after artificial abortions by dilatation and curettage in the first trimester. These samples were immediately frozen in liquid nitrogen and stored at −80°C. The renal function and blood pressure of all the women were normal, and no complications were noted in the pregnant subjects. Informed consent for this study was obtained from patients in the appropriate manner, and the study was approved by the local ethics committee.

Radioimmunoassay of hAM

RIA of hAM in plasma was performed essentially as previously reported (5), using [125I]hAM as a tracer and synthetic hAM as a standard. hAM and anti-hAM antibody were purchased from Peptide Institute Inc. (Osaka, Japan). The minimum detectable dose in the RIA was 0.5 fmol/tube (95% confidence) and the 50% binding intercept was 4.5 fmol/tube. The intra- and interassay coefficients of variation (n = 5) were 4.8% and 8.3% respectively. The cross-reactivities of the antibody were 100% with intact hAM(1–52), 10% with hAM(13–52) and hAM(1–10), and less than 0.1% with hAM(33–52), calcitonin gene-related peptide (CGRP) and amylin. No cross-reactivities were observed with various other vasoactive polypeptides. EDTA plasma samples from the women were separated by centrifugation immediately after collection and stored at −40°C. These plasma samples, acidified with equal volume of 0.1% trifluoroacetic acid (TFA), were loaded onto a Sep-pak C18 column cartridge (Waters Inc., Mildford, MA, USA). The absorbed materials were washed twice, first with 0.1% TFA and then with 10% acetonitrile–0.1% TFA. The rate of recovery of synthetic hAM was 80% after passage through the column cartridge (5).

After incubation with anti-hAM monoclonal antibody (final dilution, 1:32 000) at 4°C for 24 h, extracted samples or standard synthetic hAM were incubated with [125I]hAM at 4°C for a further 24 h. Separation of the bound from the free ligands was performed by the double-antibody method. After aspiration of the supernatant, the radioactivity of the pellets was counted. A typical standard curve for RIA of hAM was obtained.

Measurement of placenta-related steroid or peptide hormones

The concentrations of estradiol (E2), progesterone, human placental lactogen (hPL) and human chorionic gonadotropin (hCG) in the plasma of the women were measured using specific RIA kits (E2 and progesterone: Diagnostic Product Co., Los Angeles, CA, USA; hPL and hCG: Eikenkagaku Co., Tokyo, Japan). The intra- and interassay coefficients of variation of the results obtained using these four kits did not exceed 10%.

Immunohistochemistry

Immunohistochemical investigation was performed using the avidin–biotinylated horseradish peroxidase complex (ABC) method. Frozen tissue sections 5 μm thick were allowed to dry in air for 30 min, then fixed in 4% paraformaldehyde for 1 h after washing in 10 mmol/l phosphate buffered saline. All sections were then treated with methanol containing 0.3% hydrogen peroxide for 30 min. After treatment with normal goat serum for 20 min, these sections were incubated with a 1:500 dilution of the anti-hAM monoclonal antibody (Peptide Institute Inc., Osaka, Japan) and with control normal rabbit serum for 2 h in a humidified chamber at room temperature. The sections were then treated with avidin–biotin–peroxidase complex for 20 min, and stained with 0.1% diaminobenzidine tetrahydrochloride in 0.02% hydrogen peroxide. Counterstaining was performed with hematoxylin.

RNA preparation and northern blot analysis

Total RNA was extracted by the acid guanidium thiocyanate–phenol–chloroform method. Frozen tissue specimens were homogenized using a Polytron homogenizer in guanidium solution containing 4 mol/l guanidinium thiocyanate, 25 mmol/l sodium citrate, 0.5% sarcosyl and 1% 2-mercaptoethanol. Northern blot analysis was performed essentially in the same manner as described previously (13). Total RNA (20 μg) was fractionated by formaldehyde/1.1% agarose gel electrophoresis and transferred to a MagnaGraph nylon membrane (Micron Separations, Westborough, MA, USA). The cDNA probe for hAM was labeled with [32P]dCTP (Amersham Ltd, Amersham, Bucks, UK) by random primed labeling methods. After u.v. wave cross-linking, the membrane was incubated with the labeled probes at 42°C for 1 h in a hybridization buffer containing 1 mol/l NaCl, 50% formamide, 1% sodium dodecyl sulfate (SDS) and 250 μg/ml salmon sperm DNA. The membrane was washed with a solution containing 0.1×SSPE (15 mmol/l NaCl, 1 mmol/l NaH2PO4, 0.1 mmol/l EDTA)–0.5% SDS at 37°C, and autoradiographed on Kodak ZAR-1 film with an intensifying screen at −80°C for 24 h.
Statistics

Data are expressed as the mean ± S.E.M. Statistical analysis was performed by analysis of variance (ANOVA) to determine the significance of differences, with a level of \( P < 0.05 \) being accepted as statistically significant. Correlation was estimated using linear regression analysis.

Results

Concentrations of AM and correlations between AM and other hormones in maternal plasma

The mean concentrations of irAM in maternal plasma were \( 3.0 ± 0.4 \text{ fmol/ml} \) in non-pregnant periods, \( 3.4 ± 0.7 \text{ fmol/ml} \) in the first trimester, \( 3.3 ± 1.1 \text{ fmol/ml} \) in the second trimester, \( 7.3 ± 2.8 \text{ fmol/ml} \) in the third trimester and \( 4.1 ± 1.9 \text{ fmol/ml} \) in early puerperium (Fig. 1); the concentration in the third trimester was significantly greater than those in other periods. As plasma irAM increased, corresponding increases in plasma E2, progesterone and hPL concentrations were observed. Significant positive correlations were found between the concentration of irAM and those of E2 (\( r = 0.53, P < 0.05 \)), progesterone (\( r = 0.57, P < 0.001 \)) and hPL (\( r = 0.50, P < 0.05 \)); however, there was no significant correlation between irAM and hCG concentrations (Table 1).

Northern blot analysis

As shown in Fig. 3, northern blot analysis of total RNA extracted from placental tissues in the first trimester and at term revealed the presence of a distinct hybridizing band corresponding to the size of AM mRNA (1.6 kbp) in each tissue. The concentrations of AM mRNA in term placenta (villi + amnion tissue) were greater than that in villi or decidua of early pregnancy.

Discussion

This study has demonstrated changes in the concentration of irhAM in maternal plasma during human pregnancy and the expression of hAM mRNA in human placenta. The use of a specific and sensitive RIA for hAM enabled us to measure the plasma concentration of irhAM in human plasma and urine (4, 5). We were clearly measuring irhAM concentration in maternal plasma in this RIA, because the cross-reactivities of the antiserum to hAM(33–52), CGRP and amylin were much weaker than those to AM, and the plasma extract gave a parallel displacement of the label in parallel with the standard AM.

The concentration of irhAM in maternal plasma was increased in the third trimester of pregnancy, and the results appear to be comparable to those recently reported by others (6, 7). However, a recent report revealed no significant difference in mean maternal plasma concentrations of AM from week 8 to week 40 of pregnancy (14). The probable reasons for this discrepancy are the different hAM antibodies used in the RIAs, and the wide standard deviation of hAM concentrations as a result of the small sample size of our study. Our data provide evidence that the placenta produces AM and secretes it into the maternal circulation, particularly during the third trimester of pregnancy. The finding of increased concentrations in late pregnancy, followed by a significant decrease in the
puerperium, and the demonstration of AM mRNA in placenta and decidua, suggest that the placenta is a source of AM during pregnancy. We also demonstrated a significant correlation between the concentrations of irhAM and those of sex steroids or hPL, suggesting that the release of irhAM during pregnancy is a reflection of the size of the placenta. Furthermore, irhAM was detected in term amnion epithelial cells by use of an immunohistochemical procedure—a finding that is confirmed by other reports showing increased concentrations of hAM in amniotic fluid (6) and AM mRNA in feto-placental tissues of term pregnancy (11). These results suggest that AM may have an osmoregulatory role in the fetal and amniotic compartments. In this study, we demonstrated that AM mRNA was abundant in term placenta, but that smaller amounts of mRNA specific for AM were present in villi of early pregnancy. Immunostaining was positive only in term amniotic epithelium, but not in placental villi or decidua of early and term pregnancy. However, Marinoni et al. (12) have reported the presence of irhAM in extravillous trophoblasts of term placenta by immunohistochemical studies. This discrepancy in findings may be due to the low sensitivity of the immunohistochemical method in our study, and to the different procedures used for sampling the term placentae.

Our study has demonstrated that maternal plasma irhAM concentrations in the third trimester were significantly increased, compared with those in other gestational, puerperal and non-pregnant periods. However, the physiological significance of this increase in the irhAM concentrations during the third trimester remains unclear. The decreased vascular tone and the modifications to renal hemodynamics occurring during pregnancy may be attributed in part to changes in the synthesis of endothelial-derived vasoactive substances (15). It has been shown that plasma concentrations of a variety of vasoactive peptides, such as endothelin (16), prostaglandin E₂ (17) and prostacyclin (8), are increased in the third trimester, partly for the same reasons. In addition, our results suggest that the increase in plasma irhAM concentrations in the third trimester is the consequence of enhanced production of AM by the placenta.

AM has a vasodilatory effect on a variety of blood vessels in many species and may be important in controlling vascular tone in addition to local blood flow (5). The peptide also exerts a number of pharmacological effects in a variety of tissues (18), and many of its actions seem to be related to the homeostatic control of fluid, particularly electrolyte homeostasis, and the cardiovascular status in general (19). However, the physiological functions of AM in the maternal plasma during pregnancy remain unknown. Normal pregnancy is associated with a characteristic change in systemic and renal hemodynamics. The vascular endothelium generates both vasodilators and vaso-
constrictors, and a correct balance between these substances may be crucial to the adaptive changes occurring during pregnancy (9). Therefore, AM is believed to be responsible for the marked resistance to the pressor effects of angiotensin II (20) and endothelin, resulting in a modest decrease in blood pressure during the course of a normal pregnancy (21).

In conclusion, the present study has demonstrated that maternal plasma irhAM concentrations in the third trimester were significantly greater than those in other gestational periods. IrhAM was detected in term amnion epithelial cells by the use of an immunohistochemical procedure, and term placental tissue was found mainly to express AM mRNA. These results suggest that plasma irhAM may be generated partly from placental tissue, and may have a physiological role in the control of cardiovascular status and feto-placental function during human pregnancy. However, further studies are required to clarify the role of AM in the pathophysiologic characteristics of normal pregnancy.
