CLINICAL STUDY

Central ghrelin production does not substantially contribute to systemic ghrelin concentrations: a study in two subjects with active acromegaly

Abstract

Introduction: In an animal model of acromegaly (PEPCK-hGH transgenic mice), low systemic levels of ghrelin have been observed compared with normal mice. We hypothesized that systemic circulating ghrelin levels are also decreased in humans with active acromegaly and that the contribution of central ghrelin production to systemic ghrelin levels is minimal.

Objectives: The aim of the present study was to investigate, in two subjects with active acromegaly, whether there are differences between systemic ghrelin levels and ghrelin concentrations in the petrosal sinus.

Design: We measured systemic and central ghrelin levels in these two acromegalic patients by bilateral simultaneous inferior petrosal sinus sampling. Central and systemic blood samples were drawn before and 1, 5, 10, 15 and 20 min after stimulation with GH-releasing hormone (GHRH). Ghrelin was measured with a commercially available radioimmunoassay.

Results: In one acromegalic subject, the baseline systemic and central ghrelin levels were within the same range as in two non-acromegalic obese subjects. No gradient could be observed between central and systemic ghrelin concentrations. Stimulation with GHRH did not change the ghrelin concentrations in this patient. In the other acromegalic subject, the systemic ghrelin levels were also in the same range as in two non-acromegalic obese subjects. However, in this subject, baseline ghrelin concentrations in the right inferior petrosal vein were considerably lower than the systemic ghrelin concentrations, indicating a peripheral over central gradient. Administration of GHRH induced a significant rise in central ghrelin concentrations in the right inferior petrosal vein. Ghrelin levels in the left inferior petrosal vein and systemic ghrelin levels were in the normal range and GHRH stimulation did not change these concentrations.

Conclusions: The absence of a central over peripheral ghrelin gradient in these two acromegalics indicated that circulating ghrelin is mainly produced peripherally. Circulating systemic ghrelin levels were not decreased in these two subjects with active acromegaly.

Introduction

For years, regulation of growth hormone (GH) release was considered to be the net result of stimulation by GH-releasing hormone (GHRH) and inhibition by somatostatin. The discovery of ghrelin, a 28 amino acid peptide, which induces GH release *in vivo* and *in vitro*, has added another regulatory mechanism to this system (1). Ghrelin is a more potent GH secretagogue than GHRH (2). The observation that ghrelin and GHRH act synergistically suggests that these peptides have, at least partially, different mechanisms of action. However, the feedback mechanisms of ghrelin

are still unknown (2). Ghrelin is produced in the stomach and is also expressed in the hypothalamic arcuate nucleus (1). Kordon and co-workers detected ghrelin mRNA expression in normal human pituitary tissue as well as in pituitary adenomas, including somatotroph adenomas. This strongly suggests that ghrelin is produced in the pituitary gland, where it may influence the release of GH in an autocrine or paracrine manner (3, 4).

In a murine model of acromegaly (PEPCK-hGH transgenic mice), low levels of systemic ghrelin have been observed as compared with controls (5). We hypothesized that systemic ghrelin levels are also

decreased in humans with active acromegaly and that the contribution of central ghrelin production to the systemic ghrelin levels is minimal. The aim of the present study was to investigate whether there are differences between systemic ghrelin levels and ghrelin concentrations in the petrosal sinus in human acromegaly. Therefore, we measured systemic and central ghrelin levels in two acromegalic patients, who underwent bilateral simultaneous inferior petrosal sinus sampling (BSIPSS) because of diagnostic reasons.

Patients and methods

Patients and controls

Two males with active acromegaly were studied and two obese subjects without acromegaly were studied as controls. However, the body mass index (BMI) of the obese subjects (31.0 and 32.1 kg/m²) was lower than the BMI of the two acromegalics (39.2 and 34.7 kg/m²). Both acromegalic patients (56 and 51 years) presented with classical acromegalic complaints. Physical examination revealed typical acromegalic features. Serum insulin-like growth factor-I (IGF-I) levels were significantly elevated: 105 nmol/l in patient 1 and 65 nmol/l in patient 2 (normal range for age and gender: 11–35 nmol/l). Fasting insulin concentrations in these two acromegalics were 14.9 and 6.4 mU/l respectively. The diagnosis of acromegaly was confirmed in both patients by an abnormal GH response to an oral glucose tolerance load (GH > 2.5 µg/l). As these acromegalic subjects initially showed no clear pituitary abnormalities on magnetic resonance imaging (MRI) at the referring hospital, we performed BSIPSS in both subjects, at their request, to locate an adenoma. However, in the first acromegalic patient, a somatotroph pituitary adenoma of 7 mm at the right side of the pituitary could be detected by MRI at follow-up. He showed normalization in serum IGF-I after initiation of long-acting somatostatin analogue therapy as primary treatment. Also, in the second acromegalic patient, a centrally located somatotroph microadenoma was found with a diameter of 1 cm during follow-up MRI. He successfully underwent trans-sphenoidal surgery.

Two patients with centripetal obesity (one 70-year-old male and one 42-year-old female) underwent BSIPSS because of suspected Cushing's disease as part of the diagnostic work-up. Fasting insulin concentrations in these two non-acromegalic obese subjects were 29.9 and 34.6 mU/l respectively. However, after extensive testing, Cushing's syndrome could be excluded in both subjects. Cushingoid obesity was diagnosed in the male subject while polycystic ovary syndrome was diagnosed in the female subject. We therefore decided to use both of them as controls for this study. The study was performed according to the

rules of the hospital medical ethics committee. All subjects entered the study after informed consent.

BSIPSS

After an overnight fast, BSIPSS was performed via bilateral femoral vein puncture. In both inferior petrosal sinuses, a 4 French multipurpose catheter (Cordis Europe, Roden, The Netherlands) was installed and catheter position was checked by injecting small amounts of iodinated non-ionic contrast (6). Central and peripheral blood samples were drawn before and 1, 5, 10, 15 and 20 min after stimulation. Control subjects were stimulated with 1 µg/kg body weight corticotrophin-releasing hormone (CRH; Ferring, Hoofddorp, The Netherlands). The acromegalic patients were stimulated with recombinant human GHRH (Ferring) as an intravenous bolus injection (1 µg/kg).

Biochemical measurements

All blood samples were collected on ice and allowed to coagulate for 30 min. Subsequently, serum was separated by centrifugation and frozen at –20 °C. Ghrelin was measured with a commercially available radioimmunoassay (Phoenix Pharmaceuticals Inc., Belmont, CA, USA; intra-assay coefficient of variation (CV) 5.3%; interassay CV 13.6%). This radioimmunoassay uses ¹²⁵I-labelled bioactive ghrelin as a tracer molecule and a polyclonal antibody raised in rabbits against full-length octanoylated human ghrelin. In accordance with the manual no extraction procedure was performed for the ghrelin assay. In a previous study in ten healthy volunteers, we observed mean peripheral circulating ghrelin levels of 84 pmol/l (range: 35–132) (7). We used these values to compare the data of the present study.

GH was measured with a commercially available radioimmunoassay (CIS bio international, Gif-sur-Yvette Cedex, France; intra-assay CV 2.8%; interassay 4.4%).

IGF-I was measured with a commercially available immunoradiometric assay (Diagnostic Systems Laboratories Inc., Webster, TX, USA; intra-assay CV 4.9%; interassay CV 5.1%).

Results

Baseline values

In the control subjects, the baseline peripheral and central ghrelin levels were within the normal peripheral ghrelin concentration range, as previously reported (7, 8). No clear gradient could be observed between systemic and central ghrelin concentrations in the controls (Fig. 1a). In the first acromegalic subject, however, the systemic ghrelin level was well within the normal

range. The central baseline ghrelin concentration in this patient was considerably lower in the right inferior petrosal vein as compared with the systemic concentration, indicating a peripheral over central gradient. The baseline sample taken from the left inferior petrosal vein had to be discarded, because of problems in the positioning of the tip of the catheter in the hypoplastic left petrosal sinus. However, repositioning enabled us to measure ghrelin in the left petrosal sinus during GHRH stimulation (Fig. 1b). In the second acromegalic patient, the baseline peripheral and central ghrelin levels were within the normal range. Also, in this acromegalic subject, no clear differences could be observed between peripheral and central ghrelin concentrations (Fig. 1c).

Central and peripheral ghrelin levels after stimulation

No change in central or peripheral ghrelin concentrations were observed after CRH administration in both controls (Fig. 1a). As might be expected, both controls showed a significant increase in adrenocorticotrophin (ACTH) after CRH administration in both petrosal sinuses without lateralization (data not shown).

In the first acromegalic subject, administration of GHRH induced a significant rise in ghrelin concentrations in the right inferior petrosal sinus (Fig. 1b). On this side, central ghrelin rose from 19 pmol/l at baseline to a peak level of 104 pmol/l, 20 min after GHRH administration. Concomitantly, right-sided central GH levels increased from 9 ng/ml to 746 ng/ml, 20 min after stimulation (Table 1). No baseline ghrelin level in the left inferior petrosal sinus was available, because of the problems already mentioned in the positioning of the tip of the catheter. After repositioning, ghrelin levels in the left inferior petrosal sinus after GHRH stimulation showed no increase and remained about 21 pmol/l. Baseline central left-sided GH levels were not available (see above). Central left-sided GH levels rose to 418 ng/ml after GHRH stimulation (Table 1).

Figure 1 (a) Ghrelin concentration in left (■) and right (◆) pituitary and in systemic (peripheral) (*) blood at baseline and 1, 5, 10, 15 and 20 min after stimulation with CRH in control patient 1. Ghrelin concentration in left (□) and right (◇) pituitary and in peripheral (+) blood at baseline and 1, 5, 10, 15 and 20 min after stimulation with CRH in control patient 2. (b) Ghrelin concentration in left (■) and right (◆) pituitary and in systemic (peripheral) (*) blood at baseline and 1, 5, 10, 15 and 20 min after stimulation with GHRH in acromegalic patient 1. (c) Ghrelin concentration in left (■) and right (◆) pituitary and in systemic (peripheral) (*) blood at baseline and 1, 5, 10, 15 and 20 min after stimulation with GHRH in acromegalic patient 2.

Table 1 GH levels of both acromegalics (patient 1 and patient 2) at baseline and 20 min after stimulation with GHRH. The GH levels were measured in a peripheral vein and in the left and right inferior petrosal sinuses.

	GH at baseline (ng/ml)	GH 20 min after stimulation (ng/ml)
Patient 1		
Peripheral	1	31
Left	NA	418
Right	9	746
Patient 2		
Peripheral	6	16
Left	233	228
Right	213	540

NA, not assessed.

In the second acromegalic subject, central and peripheral ghrelin levels remained unchanged after GHRH stimulation (Fig. 1c). After GHRH administration, peripheral GH concentration increased from 1 ng/ml to 31 ng/ml in patient 1 and from 6 ng/ml to 16 ng/ml in patient 2 (Table 1). Peripheral ghrelin levels did not change after GHRH stimulation in these two subjects.

Discussion

Wright and co-workers (5) previously observed that systemic ghrelin levels were lower in an animal model of acromegaly. We therefore expected to find lowered systemic ghrelin levels in acromegalic subjects in whom no clear pituitary abnormalities in the MRI of the referring hospital were seen. We therefore performed BSIPSS in both subjects, at their request, to locate an adenoma. However, in the first acromegalic patient a somatotroph pituitary adenoma of 7 mm at the right side of the pituitary could be detected on an MRI at follow-up and, during follow-up MRI, in the second patient a centrally located somatotroph microadenoma was found with a diameter of 1 cm.

The baseline results of our study did not show differences in systemic ghrelin levels between the two acromegalics and the obese control subjects. Although Tschöp *et al.* (8) have reported that systemic ghrelin levels are lower in obese versus lean subjects, our acromegalics showed even higher BMI values than the obese 'controls', which might indicate that they could serve as proper controls in this study.

Systemic ghrelin levels in the acromegalic patients were not stimulated by GHRH. Our observations suggest that systemic ghrelin levels are not clearly decreased in human acromegaly despite high systemic GH concentrations. Surprisingly, in the first acromegalic patient we observed a peripheral over central gradient of more than 1.0. The cause of this gradient of more than 1.0 is not clear. Systemic samples were drawn

from the femoral vein, which is not considered to be a major source of ghrelin. In addition, an active central nervous system clearance of systemic ghrelin is not very likely. More interesting was the lateralization of pituitary ghrelin levels after GHRH stimulation in one acromegalic subject. A clear stimulation at the right side could be detected. At follow-up, an MRI revealed an ipsilateral pituitary tumor. This indicates that in this acromegalic patient no clear central overproduction of ghrelin was present and that ghrelin could still be stimulated by exogenous GHRH. In the second acromegalic patient, a centrally located somatotroph microadenoma was also found during follow-up pituitary MRI. In this patient, there was neither a gradient between baseline peripheral and central ghrelin levels nor a gradient between peripheral and central ghrelin levels after GHRH stimulation, suggesting that central ghrelin production does not substantially contribute to the systemic ghrelin level. In our normal subjects, systemic ghrelin levels also seem to be the result of peripheral ghrelin production only, as no central over peripheral gradient could be detected.

In the two healthy controls, CRH administration was not able to modify either central or systemic ghrelin levels. Ghrelin stimulates not only GH secretion, but also ACTH and prolactin secretion (2). In the two control subjects, CRH administration significantly increased both central and systemic ACTH concentrations. No direct feedback of ACTH could be found on central and systemic ghrelin levels.

In conclusion, our study suggests that, at least in some patients with active acromegaly, circulating systemic ghrelin levels are not decreased. The absence of a central over peripheral ghrelin gradient in acromegalics and controls indicates that central ghrelin production does not substantially contribute to the systemic ghrelin level.
