Abstract

Objective: Although androgenic alopecia is recognised to be a symptom of polycystic ovary syndrome (PCOS), it is not known whether polycystic ovaries (PCO) and associated endocrine abnormalities are present in patients who present with alopecia as a primary complaint. We therefore set out to determine the strength of the association between androgenic alopecia and PCO. We examined the prevalence of ultrasound-based polycystic ovarian morphology and associated clinical and biochemical features in a large multiethnic group of women whose presenting complaint was of alopecia, and in a control group.

Subjects and methods: We studied 89 women of mixed ethnic origin with androgenic alopecia and compared them to 73 control women. A detailed history was taken, anthropometry was performed and assessment of body-hair distribution was made. The presence of PCO was established by pelvic ultrasound scan. Serum gonadotrophins, testosterone, androstenedione, dihydrotestosterone and sex hormone binding globulin concentrations were measured.

Results: Women with alopecia had a higher prevalence of PCO and hirsutism than the control population (PCO: 67% vs 27%, \( P < 0.00001 \); hirsutism: 21% vs 4%, \( P = 0.003 \)). Women with alopecia (with or without PCO) had higher testosterone, androstenedione and free androgen index than controls, even though few had frankly abnormal androgens.

Conclusions: These findings confirm an association between androgenic alopecia and PCO, and other symptoms of hyperandrogenaemia. Thus most women who present with androgenic alopecia as their primary complaint also have PCO and have indices of abnormal androgen production. Since PCO is a well known risk factor for development of type 2 diabetes, this association has important implications for long-term management.

Introduction

Androgenic alopecia is one of the most common causes of hair loss in women (1). It is a slowly progressive condition that is associated with significant psychological morbidity in affected women and for which therapeutic options are limited. The diagnosis is subjective; it is based on the exclusion of other causes of hair loss and by the presence of diffuse, diminishing hair diameter, length and density (hairs per square centimetre). Female androgenic alopecia may present in several patterns. Ludwig described the preservation of the frontal hairline with progressive thinning of the crown (2). It may also take a male-pattern form of balding with bitemporal recession (3). With either pattern of hair loss, androgenic alopecia may also be characterised by diffuse reduction in the volume and density of hair.

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder to affect women of reproductive age and is, conventionally, defined as the association of hyperandrogenaemia and chronic anovulation in women with polycystic ovaries (PCO) (4, 5). Clinical hyperandrogenaemia is represented by hirsutism, acne or alopecia. Alopecia is a recognised feature of PCOS (5–9). PCO occur commonly in women with late onset acne (some studies report a prevalence of between 50 and 75% (10, 11)) and in 92% of women with idiopathic hirsutism (12), but the prevalence of PCO in women who present with alopecia is not
known. The correlation between clinical and biochemical hyperandrogenaemia is poor, probably due to individual variation in androgen sensitivity of the skin and hair follicles.

Two previous studies have looked at the association between androgenic alopecia and PCOS. Futterweit and colleagues (6) studied 109 women with alopecia. They reported a 28% prevalence of polycystic ovary ‘disease’ in their study population; however both their inclusion criteria for the study and their diagnostic criteria for PCOS were different from those used in our study. Specifically, ovarian ultrasound was not routinely used in the diagnosis of PCOS. O’Driscoll and co-workers (8) studied 350 women with ‘hirsutism or androgenic alopecia’ (the study does not specify how many women had alopecia and how many had hirsutism) and found a 60% prevalence of PCO upon ultrasound scan (8). They did not report on androgen levels apart from describing eight patients with clear-cut endocrine disorders. To further investigate the association between PCO and androgenic alopecia, we set out to establish the prevalence of PCO morphology and associated clinical and endocrine data in a large multiethnic group of women with a history of androgenic alopecia (who had presented specifically with this symptom to a trichological clinic), and to compare the prevalence in this group with that in a control group of women without alopecia.

Subjects and methods

Subjects

Between April 1998 and April 2000, 95 women with androgenic alopecia were referred to the reproductive endocrinology service at St Mary’s Hospital, London from a single trichological practice (The Philip Kingsley Clinic, London). All these women had presented initially to the clinic complaining of hair loss. The diagnosis of androgenic alopecia had been made by one of two senior consultant trichologists (GL or PK) based on Ludwig’s classification of androgenic alopecia in females (2). Diagnosis was confirmed in each case by the second consultant trichologist. The subsequent referral of consecutive patients to St Mary’s Hospital was based on the presence of alopecia and none of these women had previously found it necessary to consult a doctor for menstrual disturbances, infertility or hirsutism. None had a known diagnosis of PCOS. A serum ferritin level had been performed in all subjects prior to their referral to St Mary’s Hospital; patients with low ferritin were prescribed iron therapy by their GP, and only included in the research project if the treatment made no difference to their alopecia. Thyroid abnormalities were excluded in all participants. Of the 95 women seen, six were excluded from further analysis: three were found to have post-menopausal serum levels of gonadotrophins and three others were excluded because it was not possible to accurately determine their ovarian morphology. The subjects’ characteristics are shown in Table 1.

Over the same period, 73 control women were recruited from St Mary’s Hospital antenatal database. These were parous women who did not have a history of alopecia and formed a control cohort for a parallel study of gestational diabetes (13). They were neither pregnant nor breast-feeding at the time of the study. They had not found it necessary to consult a doctor for menstrual disturbance or hirsutism and none had a known diagnosis of PCOS. Data for this group of women have previously been published (13).

The majority of women in both alopecia and control groups were Europid in origin (63/89 with alopecia; 56/73 controls). Of the remaining women, there were more subjects of Middle-Eastern and South Asian origin in the alopecia group (n = 15) than in controls (n = 1) and fewer of Afro-Carribean origin in alopecia women (n = 2) than amongst controls (n = 14). All patients gave informed consent for the study which was approved by the ethical committee of St Mary’s NHS Trust.

Methods

All subjects were invited to attend the Metabolic Day Ward at St Mary’s Hospital, whilst in the follicular phase of the menstrual cycle when possible. A normal menstrual cycle was defined by a cycle length of between 21 and 35 days with no more than a 7 day variation between cycles in any individual. Medical history was recorded and body mass index (BMI) and waist/hip ratio (WHR) were measured. The presence of androgenic alopecia was confirmed and assessment was made of the presence and degree of hirsutism (defined as a Ferriman–Gallwrey score of eight or more). Ovarian morphology was determined by ultrasound scan carried out by one of two experienced ultrasound operators (DMW or HW) and PCO was
diagnosed according to the criteria established by Adams and colleagues (12).

Biochemical analysis was only performed on women not taking hormonal contraceptives or other medication known to affect the measured parameters. Serum lutetising hormone (LH) and follicle stimulating hormone (FSH) were measured in the follicular phase of the cycle. Testosterone, androstenedione, dihydrotestosterone (DHT) and sex hormone binding globulin (SHBG) concentrations were also measured. Serum LH and FSH were measured by the sandwich immunoassay by Bayer immuno 1 analyser (Bayer Corporation, Tarrytown, NY, USA). Interassay coefficients of variation for FSH and LH were < 2.5% (14). Testosterone was measured by radioimmunoassay as previously described (12). Androstenedione and DHT were assayed using ‘in-house’ radioimmunoassays employing ether extraction and dextran coated charcoal separation. 3H-DHT and androstenedione were obtained from Amersham Biosciences UK Ltd (Chalfont St Giles, UK). The antibody used in the DHT assay was raised in-house whilst the antibody to androstenedione was purchased from Guildhay Ltd (Guildford, UK). As the DHT antibody showed significant cross reaction with testosterone, testosterone was chemically modified to a non-cross-reacting molecule by oxidation to a glycol with potassium permanganate. During the course of this study coefficients of interassay variation for FSH and LH were < 2.5% (14). H-DHT and androstenedione were assayed using ‘in-house’ radioimmunoassays employing ether extraction and dextran coated charcoal separation. SHBG was raised in-house whilst the antibody to androstenedione was obtained from Guildhay Ltd (Guildford, UK). As the DHT antibody showed significant cross reaction with testosterone, testosterone was chemically modified to a non-cross-reacting molecule by oxidation to a glycol with potassium permanganate. During the course of this study coefficients of interassay variation for FSH and LH were < 2.5% (14). H-DHT and androstenedione were assayed using ‘in-house’ radioimmunoassays employing ether extraction and dextran coated charcoal separation. SHBG was raised in-house whilst the antibody to androstenedione was obtained from Guildhay Ltd (Guildford, UK). As the DHT antibody showed significant cross reaction with testosterone, testosterone was chemically modified to a non-cross-reacting molecule by oxidation to a glycol with potassium permanganate. During the course of this study coefficients of interassay variation for FSH and LH were < 2.5% (14). H-DHT and androstenedione were assayed using ‘in-house’ radioimmunoassays employing ether extraction and dextran coated charcoal separation.

Statistical analysis

Data are presented as medians (25th–75th centiles). Statistical analyses were performed in SPSS 10.0 for Windows using the Mann–Whitney test and χ² test, as appropriate. As the study population and the control population were not ethnically matched, logistic regression analysis was performed in order to rule out any confounding effect of ethnicity on the prevalence of PCO morphology.

Results

Comparison between women with androgenic alopecia and control subjects

Women with androgenic alopecia were younger than the control population but BMI was similar in both groups (Table 1). Of 89 women with a history of alopecia in whom ovarian morphology could be accurately assessed, 60 (67%) had PCO and among the control women 20 (27%) had PCO. The prevalence of PCO was significantly higher in women with alopecia than in the control population (χ² = 24, P < 0.00001) (Table 2). Logistic regression analysis was used to assess the relationship between alopecia and ovarian morphology, whilst allowing for ethnicity-related effects. The presence of alopecia was found to be a major determinant of PCO morphology (P < 0.001, odds ratio = 6.0), whereas ethnicity did not influence ovarian morphology (P = 0.2) in this dataset.

In women with alopecia, there was a higher prevalence of hirsutism than in the control population, and 43% of the study population had acne. The prevalence of menstrual irregularities (24%) was not significantly different from that in the control group (Table 1). Only three patients (two with PCO, one without) had both hyperandrogenaemia and irregular menses.

Even though most women had values within the normal range (only four women, three with PCO, had frankly elevated serum testosterone levels, i.e. > 3.0 nmol/l), women with alopecia had higher mean values of LH, testosterone, androstenedione concentrations and free androgen index than control women (see Table 2). There were no differences between the two groups’ FSH, DHT and SHBG concentrations.

Table 2 Ultrasound and biochemical results in patients with a primary complaint of alopecia and in normal controls. Results are expressed as median (interquartile range).

Discussion

We found that PCO were very common in a large multi-ethnic group of women with androgenetic alopecia (67% compared with 27% in the control group), confirming an association between PCO morphology and alopecia. Cases and controls were matched for BMI; the control group were older but all were premenopausal with normal serum FSH and this is unlikely to have a bearing on the prevalence of PCO or endocrine features. The majority of the patients with alopecia in this study were of normal weight and there was no difference in BMI between those with and without PCO either in the patient or control populations. This is not surprising, given that patients were recruited on the basis of a primary complaint of alopecia rather than as subjects with classic features of PCOS, amongst whom obesity tends to be more prevalent (5). When looking at the group of women with alopecia as a whole, there was a higher prevalence of hirsutism in this group than in the control population. Testosterone, androstenedione and free androgen index were also higher.

Despite the fact that most values were within the normal range, women with alopecia and PCO had indices of androgen metabolism typical of women with PCOS (ie. elevated median testosterone, androstenedione, free androgen index and lower SHBG).

These results indicate that women with alopecia have a disorder of androgen metabolism, which also manifests clinically in the higher prevalence of hirsutism than in the control population. In most, but not all, cases, alopecia was associated with the presence of PCO. It is interesting to note that androgen dependent symptoms were present even when androgen values were within the normal range. This is likely to be due to an association of increased production and increased clearance of androgens by target tissues, but this was not specifically investigated in this study.

Concentrations of DHT were no higher in women with alopecia than in controls, so measurement of this androgen appears to be no better a marker of androgenicity than total testosterone, androstenedione or free androgen index.

As mentioned in the introduction, the two previous studies that investigated the association between androgenetic alopecia and PCOS differed from ours in a number of ways, most significantly in the reason for the primary presentation. In our study, the only reason for these women seeking medical attention was the symptom of alopecia. In summary, we found that PCO occurred in two-thirds of such subjects and many, on further assessment, had other associated symptoms of hyperandrogenaemia, ie. acne and hirsutism. Biochemical indices of androgen excess, consistent with diagnosis of PCOS, were also more common in women with androgenetic alopecia than in control subjects. These findings confirm a strong association between androgenic alopecia and PCO. Thus alopecia may be the presenting complaint in women with other features of PCOS including indices of metabolic dysfunction. PCOS is a well known risk factor for development of type 2 diabetes, so this association has important implications for long-term management.
