Abstract

Objective: To present first-line thoracic surgery made possible by localization studies in three patients with ectopic parathyroid adenomas.

Design and methods: Three patients with ectopic parathyroid tissue in the mediastinum were examined by ultrasound, technetium-99m sestamibi scintigraphy, computed tomography (CT), and venous catheterization with measurement of parathyroid hormone. Without previous cervical exploration, video-assisted thoracic surgery (VATS) was used in all cases to avoid the need for thoracic open surgical procedures.

Results and conclusions: The mediastinal parathyroid glands were all detected at scintigraphy, and CT and venous catheterization were helpful in anatomic and functioning characterization. All pathologic glands were successfully resected, with only one minor complication. VATS can safely remove a deep mediastinal parathyroid adenoma and avoid more aggressive open approaches. In an experienced referral center, systematic and sophisticated imaging studies may accurately identify and localize rare ectopic parathyroid adenomas, and avoid cervical surgery.

European Journal of Endocrinology 150 141–147

Introduction

Primary hyperparathyroidism has become a frequent disease, most often detected on routine calcium screening in asymptomatic subjects (1–5). Most patients have a sporadic and solitary cervical adenoma. The operative approach was established by the 1990 consensus panel (3), and approved by a recent workshop (5): a bilateral neck exploration is performed under general anesthesia, with a thorough search for all parathyroid tissue (6–8). The use of non-invasive localization procedures is agreed after cervical surgery has failed, because the presence of an ectopic gland is more likely and because it seems to reduce the complication rate of subsequent surgery (3, 5, 9–12).

This classical strategy has recently been modified by many surgeons by the use of an accurate imaging procedure. The convergent localization of a single cervical parathyroid adenoma with both ultrasonography and technetium-99m sestamibi scintigraphy allows minimally invasive parathyroidectomy by unilateral neck exploration under local anesthesia, endoscopic parathyroidectomy or radio-guided surgery, with a success rate of 90–95% and less than 5% morbidity (13–24). This approach might facilitate the decision to operate on asymptomatic patients as often occurs in perimenopausal women, vertebral osteopenia, and vitamin D deficiency, as well as in subjects who are elderly and have poor health status (4, 8, 13–15, 25–30).

Another major interest of systematic preoperative imaging is the discovery of ectopic adenomas requiring a trans-sternal or transthoracic approach, which are present in 1.25–2% of patients (31–36). In such cases, an optimal strategy would be to perform a first-line thoracoscopic approach.

We report here our experience in three cases of ectopic parathyroid glands successfully resected by video-assisted thoracic surgery (VATS) performed as a first-line treatment.

Methods

Preoperative cervical ultrasound and Tc99m-sestamibi scintigraphy for primary hyperparathyroidism have been performed in all patients in our Department since 1993, always by the same operator (B R). After placing the patient in the supine position with the neck slightly extended, a complete sonographic survey
is begun just above the suprasternal notch and con- 
tinued superiorly to the upper border of the larynx, with a 
linear 7.5 MHz transducer operating in black and with 
imaging and color doppler. A parathyroid adenoma 
appears as an oval hypoechoicogenic mass, sometimes 
containing cystic components, it is located adjacent to 
the thyroid gland, and it is mobile during swallowing. 
Obviously, deep mediastinal parathyroid lesions are 
inaccessible by ultrasound.

Double-phase Tc99m-sestamibi (technetium-hexi-
sis,2-methoxy-isobutyl-isonitrile; Cardiolite) scintigra-
phy (37–39) was also routinely performed. Neck and 
mediastinum images were acquired with a low-energy, 
high-resolution collimator, 5 – 15 min and 90 min after 
550 – 740 MBq Tc99m-sestamibi were intravenously 
jected. Images are recorded into a 256 × 256 matrix. A parathyroid adenoma appears as an area of 
increased activity seen on initial image and persisting 
on delayed images, in contrast to thyroid tissue in 
which the tracer is more quickly washed out. In each 
ase of suspected ectopic mediastinal adenoma, antero-
posterior planar and frontal, coronal, sagittal single-
photon emission computerized tomography (SPECT) 
images are also performed for better anatomic localiz-
ation. Images are acquired in a matrix size of 
128 × 128, a 3° angle step, and a time of 20 s per frame.

Computed tomography (CT) scan sections were 
obtained at 5 mm intervals from the level of the angle 
of the mandible to the aortic arch before and after 
the intravenous administration of contrast agent. 
A parathyroid adenoma usually appears as a rounded, 
well-defined, homogeneous hypodense mass, raised in 
an intense way after injection at arterial time, but 
shorter compared to the vessels or the thyroid.

Because thoracic ectopic adenoma was suspected 
after the above imaging studies, venous catheterization 
of large veins in the neck and the mediastinum for the 
determination of parathyroid hormone (PTH) was per- 
formed as described previously (11), with a significant 
gradient when the local PTH level was at least twice 
the peripheral PTH value.

VATS was performed under general anesthesia using 
a double-lumen endotracheal tube by a single surgeon 
(P.B). The patients were ventilated only via the opposite 
lung and were kept in a full lateral position. Three 
trocars were placed from the side of the chest of the 
lung and were kept in a full lateral position. Three 
(P.B). The patients were ventilated only via the opposite 
via a double-lumen endotracheal tube by a single surgeon 
(within a factor II deficit). Table 1 summarizes the biological 
data. She had silent renal stones. The absence of a 
familial history and the lack of association with other 
endocrine diseases such as pancreatic islet-cell, anterior 
pituitary and adrenal cortex lesions almost eliminated 
the diagnosis of multiple endocrine neoplasia 
(MEN)-1. No parathyroid tumor was identified with cer-
vical ultrasound. The Tc99m-sestamibi parathyroid 
scintigraphy and SPECT demonstrated a focal area of 
increased uptake involving the right inferior side of 
the anterior mediastinum, which suggested an ectopic 
mediastinal parathyroid adenoma (Figs 1 and 2). CT 
showed a 1 cm mass located in front of the ascending 
aorta and superior vena cava (Fig. 3). The venous 
catheterization with measurement of the PTH level 
revealed a gradient with a step-up value crossing the 
right brachiocephalic vein and the superior vena 
cava. The diagnosis of a solitary mediastinal adenoma 
located in the inferior part of anterior mediastinum 
was made and VATS was performed. No abnormal 
tissue could be visualized in the anterior mediastinum 
during surgery. The surgeon, guided by the preopera-
tive localization, made a large surgical resection of 
perivisceral fat tissue, including the thymus and 
mediastinal pleura covering the superior vena cava, 
aortic arch, and right atrium. A drop (from 146 to 
4 ng/l) in PTH levels occurred during the surgery , 
suggesting the removal of all hyperfunctioning tissue. 
The final pathology confirmed a 1 cm parathyroid 
tumor. The patient’s serum ionized calcium has been 
normalized since the surgery at follow-up at 12 
months, without any complications.

Results

**Patient no. 1**

A primary hyperparathyroidism was diagnosed during 
a routine laboratory screening in a 36-year-old 
woman admitted for phlebitis (eventually correlated to 
a factor II deficit). Table 1 summarizes the biological 
data. She had silent renal stones. The absence of a 
familial history and the lack of association with other 
endocrine diseases such as pancreatic islet-cell, anterior 
pituitary and adrenal cortex lesions almost eliminated 
the diagnosis of multiple endocrine neoplasia 
(MEN)-1. No parathyroid tumor was identified with cer-
vical ultrasound. The Tc99m-sestamibi parathyroid 
scintigraphy and SPECT demonstrated a focal area of 
increased uptake involving the right inferior side of 
the anterior mediastinum, which suggested an ectopic 
mediastinal parathyroid adenoma (Figs 1 and 2). CT 
showed a 1 cm mass located in front of the ascending 
aorta and superior vena cava (Fig. 3). The venous 
catheterization with measurement of the PTH level 
revealed a gradient with a step-up value crossing the 
right brachiocephalic vein and the superior vena 
cava. The diagnosis of a solitary mediastinal adenoma 
located in the inferior part of anterior mediastinum 
was made and VATS was performed. No abnormal 
tissue could be visualized in the anterior mediastinum 
during surgery. The surgeon, guided by the preopera-
tive localization, made a large surgical resection of 
perivisceral fat tissue, including the thymus and 
mediastinal pleura covering the superior vena cava, 
aortic arch, and right atrium. A drop (from 146 to 
4 ng/l) in PTH levels occurred during the surgery , 
suggesting the removal of all hyperfunctioning tissue. 
The final pathology confirmed a 1 cm parathyroid 
tumor. The patient’s serum ionized calcium has been 
normalized since the surgery at follow-up at 12 
months, without any complications.

**Patient no. 2**

The survey of a 57-year-old woman with a history of 
breast cancer diagnosed 2 years earlier and considered
to be cured showed a primary hyperparathyroidism (Table 1). There was no indication of genetic disease. The cervical ultrasound detected no parathyroid mass. The Tc99m-sestamibi parathyroid scintigraphy demonstrated a focal area of increased uptake involving the right anterior mediastinum that suggested an ectopic parathyroid adenoma. The CT visualized two masses, one anterior mass looking like a hamartochondroma and an ovoid mass of 2 cm in front of the superior vena cava and ascending aorta corresponding to the image seen by scintigraphy and to the increases in the PTH level shown by venous catheterization. Using VATS, dissection of the adipose tissue in the upper anterior mediastinum was carried out and the PTH level decreased intraoperatively (from 777 to 41 ng/l). No postoperative complication occurred. A hypercellular parathyroid gland was found inside the fat tissue. Since there was no normal parathyroid tissue around, we cannot give a precise diagnosis between adenoma and hyperplasia. Serum ionized calcium has been normalized since surgery at follow-up at 31 months.

**Patient no. 3**

Primary hyperparathyroidism was diagnosed in an 82-year-old woman followed for wrist pain (Table 1). Her past medical history revealed no endocrine disease.

but an atrial fibrillation for years. The cervical ultrasound was negative. The Tc99m-sestamibi scintigraphy revealed two locations of increased uptake: one dubious with regard to the left lobe of the thyroid and one in the upper left mediastinum. CT visualized one mass located near the thyroid which did not take the contrast as much as the rest of the thyroid, suggesting a thyroid adenoma, and a 1 cm node located above the aortic arch. The catheterization confirmed this diagnosis with an increase in the PTH level in the superior vena cava. Using VATS, the surgeon removed the adipose tissue in front of the aorta, which contained a 1 cm adenoma. The patient normalized her ionized calcium level, but developed transient hoarseness presumed to be due to damage to the left recurrent laryngeal nerve, which loops around the aortic arch.

Discussion

The possible sites of ectopic parathyroid tissue are parapharyngeal at the level of the mandible, intrathyroidal, and mediastinal. Most ectopic parathyroid adenomas are found in close approximation to the thymus gland (9, 31, 32, 36, 40–43) and can be excised using a collar incision. Parathyroid adenomas deeper in the chest require a sternotomy or lateral thoracotomy (32, 41, 42, 44–48), angiographic ablation (49, 50), video-assisted mediastinal or thoracoscopic surgery (VAMS/VATS), or even an infrasternal approach in patients with pleural adhesions or pulmonary insufficiency (51, 52). VATS, developed by Landreneau et al. (53), is safe, offers the advantages of minimal invasive surgery, and does not interfere with other surgical approaches, with lower risks of re-operation. There are several reports in the literature of successful resections of ectopic parathyroid tissue using VATS, with rare complications (12, 34–36, 43, 48, 54–62).

Preoperative localization tests being seldom used when a standard surgical approach is used, only a few patients have undergone first-line resection of mediastinal adenoma. Less than ten patients have been reported until now (36, 47, 48, 54, 56–59, 61, 62). Cupisti et al. (36) recommended VATS as the first procedure only if the adenoma is clearly located in the chest deeper than the brachiocephalic vein. Furthermore, scintigraphic images were rarely further investigated to exclude non-specific fixation, by arteriography, selective venous catheterization, intraoperative PTH assay or radioguided dissection (36, 47, 60, 62). More often, only the CT scan was performed because the size of the solid structure was more than 15 mm.

In our center, once the diagnosis of hyperparathyroidism has been confirmed, cervical ultrasonography and planar sestamibi scintigraphy are systematically performed. If both examinations are concurrent for a single cervical adenoma, unilateral neck exploration under local anesthesia is proposed, except in cases of suspected multiple abnormal parathyroid glands, familial hyperparathyroidism and/or MEN, coexistence of a thyroid disease requiring surgery, history of childhood irradiation to the neck and the head, allergy to local anesthetic drugs, severe psychiatric illness, and deafness. If, after the removal of the adenoma, the intraoperative PTH level falls by more than 50% with a final value that is within the normal range, the operation is terminated. If the intraoperative PTH does not fall and the patient has an indication for surgery as defined by the recent consensus, the operation is extended to seek all parathyroid glands. If ultrasonography is negative and planar scintigraphy shows mediastinal fixation, anatomic and functional characterization are further performed with SPECT, CT scan, venous catheterization, and intraoperative PTH assays. Indeed, a mediastinal focal area of uptake at scintigraphy without cervical fixation or ultrasound image may be a false positive of scintigraphy and a false negative of ultrasonography. In experienced hands, the main false negatives of cervical ultrasonography are explained by the small size of the parathyroid adenomas, misinterpretation of an intrathyroid image, retrooesophageal, retropharyngotracheal or mediastinal localization, coexisting multinodular goiter, or postoperative changes. False positives of Tc99m-sestamibi scintigraphy at the mediastinal level are mainly tumoral (metastatic thyroid cancer, lung cancer, bone or lymph node metastases, thymoma) or inflammatory lesions (28, 63). For the second patient, even if the breast cancer was considered in remission, a metastatic node in the inferior mammary chain could not be ruled out. In addition, the superior portion of the right atrium and basal superoanterior right ventricular myocardium often appear as discrete isolated foci on Tc99m-sestamibi scintigraphy because they are considerably thicker than other parts of the right atrial and right ventricular muscle respectively, and because they are seen partly.

**Figure 3** CT scan showing a parathyroid adenoma (arrow) in front of the ascending aorta in patient no. 1.
end-on in the anterior projection (64). Another potential pitfall is due to central venous pacemaker wires (65). False negative studies are more common in patients with small hyperplastic parathyroid glands and multiglandular disease (39, 64).

CT demonstrated tissue lesions with the features of parathyroid tissue (but not of lymph node in the second case) corresponding to scintigraphic uptake, and defined the precise anatomic localization. Positive venous catheterization, with a technique having low morbidity and high sensitivity (11, 66), was consistent with parathyroid tissue. CT and catheterization allowed us to exclude false-positive scintigraphy. A combination of scintigraphy and CT being concurrent, however, the use of catheterization might be discussed. Recent studies indicate that simultaneous acquisition of SPECT and CT images using the same imaging device provides a better anatomic localization (67, 68).

In our cases, the diagnosis of mediastinal parathyroid adenoma was made on the grounds of consistent imaging data. The patients had indications for surgery: the first one was young and had urinary stones; the second one had osteoporosis; the last one had calcemia 0.25 mmol/l above the normal reference range and osteoporosis. Definitive surgical approach by first-line thoracotomy was planned. A dramatic decrease of intraoperative PTH values predicted a successful outcome, avoiding the need to extend resection because of the surgeon’s inability to accurately visualize parathyroid glands in the mediastinal tissue and without localization of all glands in the neck.

Routine preoperative imaging with neck ultrasonography and scintigraphy allows the avoidance of exploration of the neck in cases of an ectopic parathyroid adenoma. In the case of negative neck ultrasonography combined with an ectopic image at scintigraphy, a CT scan should be performed in order to localize the image with more precision. Concurrent studies permit the removal of the mediastinal parathyroid tumor by first-line thoracic surgery, confirmed by the intraoperative measurement of PTH. Furthermore, a study made in the USA (69) demonstrated that routine preoperative localization with Tc99m-sestamibi and ultrasound scans is not more expensive than the cumulative costs of failure to identify the ectopic parathyroid adenoma when exploration without preoperative localization is performed. Our results stress the usefulness of this strategy.
