Abstract

Objective: The mechanisms regulating the anabolic response of the skeleton to intermittent exogenous parathyroid hormone (PTH) administration are not fully elucidated. The aim of this prospective study was to evaluate the acute effect (up to 1 month) of teriparatide (TPTD; human recombinant PTH 1–34) on serum levels of osteoprotegerin (OPG) and receptor activator for nuclear factor-κB ligand (RANKL) in women with established osteoporosis.

Design: Twenty-three postmenopausal Caucasian women with established osteoporosis (mean age 66.7 ± 1.6 years) received daily injections of 20 μg TPTD for 12 months.

Methods: Serum samples for total calcium (Ca), phosphate, alkaline phosphatase, N-terminal propeptide of type I collagen, intact PTH (iPTH), OPG, and RANKL were obtained at baseline, 1 h, 1 day, and 1 month after initiation of therapy. Lumbar spine bone mineral density (BMD) was measured before and 12 months after TPTD treatment.

Results: Serum total Ca increased and iPTH gradually decreased with TPTD treatment. Serum OPG levels remained unchanged, while RANKL increased gradually during the study (P < 0.001). There was no correlation between OPG or RANKL and BMD changes or iPTH levels.

Conclusions: TPTD therapy in women with postmenopausal osteoporosis results in acute increase in serum RANKL levels but does not affect serum OPG. These changes may reflect an increase in the number of active osteoblasts with therapy and might be responsible for the acceleration of bone turnover rate that characterizes TPTD.

European Journal of Endocrinology 158 411–415

Introduction

Parathyroid hormone (PTH) exerts a catabolic effect on the skeleton in the case of continuous hypersecretion, such as in primary hyperparathyroidism. On the contrary, intermittent administration of teriparatide (TPTD; recombinant human PTH 1–34) exerts an osteoanabolic effect characterized by direct effects on bone formation through stimulation of osteoblast activity and inhibition of their apoptosis (1). Nevertheless, the mechanisms regulating the anabolic response of TPTD to the skeleton are not fully elucidated.

The system of osteoprotegerin (OPG), receptor activator for nuclear factor-κB (RANK) and its ligand (RANKL) plays a central role in the pathophysiology of osteoporosis. RANKL, expressed by the pre-osteoblasts and stromal cells, binds to RANK, expressed by cells of the osteoclast lineage, inducing a signaling cascade leading to the differentiation and fusion of osteoclast precursor cells and stimulating the activity of the mature osteoclast (2). The effects of RANKL are counteracted by OPG, a soluble neutralizing decoy receptor. OPG and RANKL production by the osteoblasts is regulated by a number of cytokines and hormones, including PTH (3). RANKL is expressed preferably by undifferentiated osteoblasts. As the osteoblasts differentiate, RANKL mRNA levels decrease and OPG levels increase (2). Therapies that modify bone turnover are expected to influence the production of OPG and RANKL.

In vitro studies in both animal and human osteoblasts indicate that PTH decreases (4–6) or does not affect OPG (7) and increases RANKL production (4–6). Intracellular calcium (Ca) elevations seem to mediate these actions on OPG/RANKL expression (8). In vivo animal studies showed that PTH, delivered either intermittently (9, 10) or continuously (11, 12), leads to increased expression of RANKL gene, while OPG expression seems...
not to be altered (12). Similarly, in patients with hyperparathyroidism, bone biopsies showed an increase in RANKL and a decrease in OPG gene expression, which was reversed after parathyroidectomy (13), although serum OPG did not correlate with PTH before surgery and was not affected by parathyroidectomy (14). In another study, endogenous PTH levels were negatively associated with OPG expression, but also, surprisingly, with RANKL expression in human bone tissue in vivo (15). Only one study has examined the long-term effects of TPTD on serum OPG and RANKL levels in humans with glucocorticoid-induced osteoporosis (16). In this study, Buxton et al. reported an early-onset significant increase in serum RANKL, followed by a mild decrease in OPG. To the best of our knowledge, no study has reported on the acute impact of TPTD in OPG/RANKL serum levels.

The aim of this prospective study was to evaluate the acute effect of TPTD administration on serum OPG and RANKL levels, in women with established osteoporosis.

**Patients and methods**

**Patients**

Patients were recruited at the outpatient clinics of the Department of Endocrinology, Hippocratism General Hospital, Thessaloniki, Greece, a tertiary referral center for metabolic bone diseases. Twenty-three consecutive postmenopausal Caucasian women (age 66.7 ± 1.6 years, age at menopause 45.2 ± 1.0 years) with established osteoporosis were included. Established osteoporosis was defined as a T-score of less than −2.5 (mean − 3.1 ± 0.2) at the lumbar spine and the presence of at least one vertebral or non-vertebral fracture (mean 1.4 ± 0.1 fractures). Exclusion criteria were: i) secondary osteoporosis, ii) diseases that could affect bone metabolism, and iii) medications that could affect bone metabolism. Women receiving any anti-osteoporotic treatment during the last 6 months were excluded as well. All patients were receiving 500 mg elemental Ca and 400 IU vitamin D daily throughout the study. Patients’ baseline characteristics are given in Table 1. This study was approved by the Ethics Committee of Hippocratism General Hospital.

**Methods**

Baseline assessment included history, clinical evaluation, and body mass index (BMI). Morning fasting blood samples were obtained from all women before (baseline), 1 h, 1 day, and 1 month after initiation of treatment. The samples were centrifuged immediately and serum was separated and stored at −30°C; all measurements were performed simultaneously at the end of the study. Studied parameters included serum levels of total Ca, phosphate (P), total alkaline phosphatase (ALP; COBAS INTEGRA ALP IFCC; Roche Diagnostics), intact PTH (iPTH; ECLIA, Elecsys PTH, Roche Diagnostics), OPG (ELISA; Ray Biotech Inc., Norcross, Georgia, USA; sensitivity 0.02 pmol/l, intra-assay coefficient of variation (CV) <10%, inter-assay CV <12%), and RANKL (ELISA; Biomedica, Wien, Austria; sensitivity 0.08 pmol/l, intra-assay CV <3−5%, inter-assay CV <6−9%). The OPG assay detects all three different forms of circulating OPG (monomer, dimer, and RANKL/OPG complex). Serum N-terminal propeptide of type I collagen (PINP; ECLIA, Elecsys total PINP; Roche Diagnostics), a more specific bone formation marker, was also measured at baseline and 1 month in order to verify TPTD effects and compliance.

Lumbar spine bone mineral density (BMD) was measured by dual energy X-ray absorptiometry using a DPX-IQ densitometer (Lunar Corporation, Madison, WI, USA) before and 12 months after initiation of treatment.

Statistical analysis

Based on a pilot study of our group, regarding baseline and post-treatment levels of study variables, we assumed the following _a priori_ levels: serum RANKL at baseline, 0.500 ± 0.100 pmol/l (mean ± S.E.M.) and serum RANKL at month 1, 0.750 ± 0.100 pmol/l. On the basis of these assumptions, we needed to enroll 20 women for the study to have a power of 80% with a type I error rate of 0.05 to detect a 0.250 pmol/l absolute difference in serum RANKL levels at different time points.

Data are presented as mean ± S.E.M. Study parameters were of normal distribution or transformed, as revealed by the Kolmogorov–Smirnov test. The general linear model (repeated measures) was used to identify differences within the group, with Bonferroni as _post hoc_ test. Pearson’s test was used for correlation between variables. _P_<0.05 was considered statistically significant. Study power was calculated with Gpower 3 (Universität Kiel, Germany). Statistical analysis was performed via free access.
performed with SPSS 15 for Windows (SPSS Inc., Chicago, Illinois, USA).

Results

Serum total Ca increased at hour 1 after the first injection, returned to baseline values on day 1, and was significantly higher at month 1 when compared with baseline levels. Serum P and ALP gradually increased throughout the study, reaching statistical significance at month 1. Serum P1NP was also significantly higher at month 1 when compared with baseline levels. iPTH acutely decreased by 19.5% already at hour 1 after the first injection and the reduction reached 32.6% at month 1. Serum RANKL increased rapidly after the first injection and continued increasing towards month 1. On the contrary, serum OPG levels remained unchanged throughout the study. OPG/RANKL ratio decreased significantly as a consequence of the significant increase in serum RANKL. All acute (up to 1 month) changes in total Ca, P, ALP, P1NP, iPTH, OPG, RANKL, and OPG/RANKL ratio are given in Table 2. Mean percent changes of serum OPG and RANKL throughout the study are illustrated in Fig. 1.

Lumbar spine BMD increased significantly in TPTD-treated women during the first year of treatment (BMD at baseline: 0.758 ± 0.034 g/cm² versus BMD after 12 months: 0.812 ± 0.031 g/cm², P < 0.001 (increased by 7.1%); T-score at baseline: −3.1 ± 0.2 versus T-score after 12 months: −2.8 ± 0.2, P = 0.001).

No correlation was observed between serum OPG or RANKL and iPTH levels and between baseline OPG or RANKL levels and age, BMI, or BMD at baseline.

Discussion

Since the development of assays for OPG and RANKL, there has been considerable interest in their use as markers of metabolic bone disease and its treatment (17, 18). However, there are few convincing data that demonstrate a response of serum OPG and RANKL to therapy. A potential change in the cellular response of serum OPG or RANKL to therapy may be masked by a concurrent change in the number of active osteoblasts as bone turnover is altered. In the studies where a change in OPG has been observed, measurements have often been made within a few days after initiation of treatment, before the changes in bone turnover have been established (19). Many of these studies were of a retrospective design. Therefore, we designed a prospective study, aiming to evaluate acute (up to 1 month) changes in serum levels of OPG, RANKL, and OPG/RANKL ratio after administration of TPTD in postmenopausal women with established osteoporosis.

In our study, the changes in serum total ALP and P1NP at 1 month and BMD at 12 months were similar to that observed in larger studies (20, 21), confirming the action of TPTD on bone turnover, and providing evidence of patients’ compliance to treatment.

iPTH levels were gradually decreasing throughout the study. Similar reduction in endogenous PTH was observed acutely after TPTD infusion in normal (22) and osteoporotic women (23). iPTH decrease can be attributed to the suppressive effect of TPTD. Two conclusions can be made from these data: i) administration of 20 μg TPTD daily is sufficient enough to inhibit endogenous hormone release from the parathyroid glands and ii) the amino-terminal end of PTH is the part of the molecule that exerts the negative feedback to the parathyroid glands.

There are serious concerns regarding the use of serum OPG and RANKL as markers of anti-osteoporotic effect on bone. First, serum OPG and RANKL may not reflect the levels and activity of these cytokines in the bone microenvironment, since a small amount of locally acting cytokines leak to systemic circulation (18). Secondly, a part of serum OPG and RANKL may originate from non-skeletal sources (18). Thirdly, the specificity of current commercially available assays to detect OPG is questioned, as they have been designed to detect all forms of OPG (monomer, dimer, RANKL/OPG complex) and not exclusively the dimeric form, which is thought to be the biologically active one (24). Fourthly, serum RANKL constitutes only a small part of total

Data are shown as mean ± S.E.M. P values are calculated by the general linear model (repeated measures). *P < 0.05 versus baseline, †P < 0.05 versus hour 1, ‡P < 0.05 versus day 1 (Bonferroni post hoc test), Ca, calcium; P, phosphate; ALP, alkaline phosphate; P1NP, N-terminal propeptide of type I collagen; iPTH, intact parathyroid hormone; OPG, osteoprotegerin; RANKL, receptor activator for nuclear factor-κB ligand.
RANKL, as the majority is cell bound and thus not detectable in the circulation. Cell surface production of RANKL can be assessed in vivo in humans by flow cytometry (25), an impractical method that usually requires bone biopsy; even if performed in peripheral blood, local (i.e., bone marrow) production of RANKL is probably the most relevant. However, in our study, serum RANKL levels, as opposed to OPG levels, changed significantly after TPTD administration.

In accordance with our results, several in vitro studies have found that PTH administration increases RANKL mRNA expression and protein levels in the osteoblasts (4–6), while it decreases (4–6) or does not affect OPG (7). Furthermore, in animal studies, an increased expression of RANKL gene following intermittent (9, 10) or continuous (11, 12) PTH administration has been reported, although OPG expression was not altered (12).

Only one study has examined TPTD effect on serum OPG and RANKL levels in humans with glucocorticoid-induced osteoporosis, but on a chronic basis (16). In this study, a significant increase in serum RANKL (within 1 month after initiation of therapy) and a mild decrease in OPG (within 6 months after initiation of therapy) were reported. Our findings are in accordance with this study, although it dealt with glucocorticoid-induced osteoporosis, women were treated with 40 μg TPTD daily, hormone replacement therapy was prescribed in addition to TPTD to both controls and patients, and blood samples had been subjected to two freeze–thaw cycles before analyzed with a different assay (ALPCO Diagnostics, Windham, NH, USA).

The changes in serum RANKL levels with TPTD may result from the increase in the number of active osteoblasts caused by the therapy. As the number of active osteoblasts is increasing, RANKL production increases as well, leading to the activation of the osteoclasts and the acceleration of bone turnover rate that characterizes TPTD action on the skeleton. However, extremely rapid (within 1 h) changes in serum RANKL might be the result of shedding of membrane-bound RANKL, given that the increase in active osteoblasts number is not yet feasible. The anabolic effect of TPTD is possibly not exerted by the OPG/RANKL/RANK system, which regulates osteoclast activity, but by other cytokines that regulate osteoblast activity, such as insulin-like growth factor-I (IGF-I) or insulin-like growth factor-II IGF-II (26–28). IGF-I may act as a coupling factor in bone remodeling by activating both bone formation, acting directly on the osteoblasts, and bone resorption, acting indirectly on the osteoclasts through the OPG/RANKL/RANK system (26).

In conclusion, the TPTD therapy in women with postmenopausal osteoporosis results in acute increase in serum RANKL levels but does not affect serum OPG. These changes may reflect an increase in the number of active osteoblasts with therapy and might be responsible for the acceleration of bone turnover rate that characterizes TPTD.
