Abstract

Context: Acid-labile subunit (ALS) deficiency due to homozygous inactivation of the ALS gene (IGFALS) is associated with moderate short stature, and in few cases pubertal delay. The clinical expression of heterozygosity is unknown.

Objective: To investigate the clinical, laboratory, and radiological features of homozygous and heterozygous carriers of a novel mutation in the ALS gene in comparison with non-carriers.

Subjects: Three short Kurdish brothers and their relatives.

Results: The index cases presented with short stature, microcephaly, and low circulating IGF-I and IGFBP-3, and undetectable ALS levels. Two were known with a low bone mineral density and one of them had suffered from two fractures. We found a novel homozygous ALS gene mutation resulting in a premature stop codon (c.1490dupT, p.Leu497PhefsX40). The IGF-I, IGFBP-3, and ALS 150 kDa ternary complex was absent, and ALS proteins in serum were not detected with western blot. IGFBP-1 and IGFBP-2 were low and there was a mild insulin resistance. Five heterozygous carriers tended to have a lower height and head circumference than five non-carriers, and had low plasma ALS and IGFBP-3 levels. Bone mineral (apparent) density was low in two out of three homozygous carriers, and also in four out of nine relatives.

Conclusions: The clinical presentation of homozygous ALS mutations may, besides short stature, include microcephaly. Heterozygous carriers may have less statural and head growth, suggestive for a gene dosage effect.

European Journal of Endocrinology 159 113–120

Introduction

For both humans and rodents, it has been well established that insulin-like growth factor-I (IGF-I) plays a critical role in the regulation of intrauterine growth and development and postnatal growth and metabolism (1, 2). Total IGF-I deficiency leads to severe intrauterine and postnatal growth failure, microcephaly, mental retardation, and deafness (3, 4). Partial IGF-I resistance due to heterozygous mutations in the IGF-I receptor (IGF1R) gene results in moderate intrauterine and postnatal growth retardation and microcephaly (5–8).

A third defect that is associated with a reduced bioavailability of IGF-I is caused by a mutation in the acid-labile subunit gene (ALS). ALS can form, together with IGF-I (or IGF-II) and IGFBP-3 (IGFBP-3, or IGFBP-5 for only 10%), a 150 kDa ternary complex. Under normal circumstances, 80–85% of circulating IGF-I is retained in this complex (9). The 150 kDa complexes cannot cross the capillary endothelial barrier, which prolongs the half-life of IGFs, IGFBP-3 and IGFBP-5, in the circulation (9–11). This seems to play an important role in the regulation of the bioavailability of IGFs to the tissue compartments.

ALS belongs to the superfamily of leucine-rich repeat (LRR) proteins, characterized by their ability to participate in protein–protein interactions. About 75% of the mature protein consists of the consensus motif for the LRR superfamily of proteins. These leucine-rich domains organize ALS into a doughnut-shaped structure (11, 12). Whereas ALS readily binds to binary complexes of IGFs and IGFBP-3, it does not interact directly with free IGFs and shows only a very low affinity for unliganded IGFBP-3 (13, 14).
So far, eight patients have been described with mutations in theALSgene (10, 15–18). All cases described were characterized by moderate or mild growth failure, undetectable or very low circulating levels of ALS, and markedly reduced plasma concentrations of IGFBP-3 and IGF-I. In some cases, pubertal delay was noted, and a low bone mineral density (BMD) was found in one case (19).

In this report, we describe three brothers of Kurdish origin with short stature and microcephaly associated with a novel homozygous mutation in theALSgene. In addition, we have evaluated the clinical and laboratory findings in ten relatives, five of whom were heterozygous for the mutation and five non-carriers.

**Methods**

All subjects described in this paper belong to a consanguineous family of Kurdish origin (Fig. 1). After mutation analysis, the subjects were divided into ‘patients’ (homozygous carriers), heterozygous carriers, and non-carriers. For each homozygous carrier, the medical history as well as the results of previous investigations was retrieved. In 2007, all the subjects were again thoroughly investigated. All the subjects provided written informed consent.

**Molecular studies**

Genomic DNA was isolated from whole blood or buffy coats according to the salting out procedure described by Miller et al. (20). All exons ofALS(GenBank accession number AF192554) were PCR amplified and sequenced as described previously (4). The various primer sequences employed are available upon request.

**Clinical measurements and auxology**

Physical examination was performed including measurements of height and sitting height with a Harpenden stadiometer and head circumference with a tape measure.

![Figure 1](https://www.eje-online.org)  
**Figure 1** Pedigree of the family. The patients are indicated in black and the heterozygous carriers are indicated in white/black. On the left, the generation number is indicated and the family number is indicated below each individual.

Height was expressed as SDS based on references for Turkish children living in the Netherlands (21). Head circumference and sitting height/height ratio were expressed as SDS for the Dutch population (22, 23). Differences between homozygous, heterozygous, and non-carriers were calculated with ANOVA.

**Radiological measurements**

BMD was measured by dual energy X-ray absorptiometry using the Hologic Scanner (QDR 4500W) at the lumbar spine, femoral neck, and total body. The volumetric bone mineral apparent density (BMAD) was calculated using the formula: BMAD (g/cm²) = BMD × (4/π × width of measurement area in lumbar spine) (24). An estimate of the mean width was derived from the scanned area (cm²) divided by the height of L2–L4. z-Scores were calculated using the reference data as reported by Fournier et al. (25). Subjects above the age of 20 years were compared with the reference data of the subjects aged 18–20 years. The z-score of the subjects below the age of 9 years could not be calculated because there were no appropriate references.

**Biochemical measurements**

Plasma levels of IGF-I, IGF-II, IGFBP-1, IGFBP-2, IGFBP-3, IGFBP-4, and IGFBP-6 were determined as described previously (4), and ALS was measured by a commercially available ELISA kit (DSL, Inc., Webster, TX, USA) (26). All measurements were expressed as SDS, except for IGFBP-1 in adults older than 24 years, which was compared with a reference group of six healthy adult controls. The different molecular size classes of endogenous IGF–IGFBP complexes in plasma were determined by neutral gel filtration through a 1.6 × 60 cm Hi-Load Superdex-200 column. Prior to column chromatography, each serum sample (250 μl) was incubated with 100 μl of either ~80 000 c.p.m. 125I-hIGF-I or 125I-IGF-II, being dissolved in 50 mM sodium phosphate buffer (pH 7.4), containing 0.2% BSA, 10 mM EDTA, and 0.05% (w/v) Tween-20, for 17 h at 4 °C. The various molecular size classes of complexes were eluted from the column at a rate of 1.2 ml/min using 0.05 M NH₄HCO₃ buffer (pH 7.4). The 125I content of each 1.2 ml fraction was counted in a γ-counter. The hIGFBP-3 used in several of these experiments was isolated from human plasma according to Martin and Baxter (27). Western blotting on serum samples was performed as described previously (28), using an antibody against human amino-terminal ALS-1–14 (DSL, Inc).

**Results**

**Medical history of the ALS-deficient patients**

Patient III-1 was born as the first of four children of consanguineous parents. In the first three years, he was
short, frequently ill, had many episodes of diarrhea, and showed poor appetite and night sweating. At the age of 11.6 years, he moved with his family to the Netherlands. At the age of 12 and 14 years, he suffered fractures of the left wrist and arm, after minor trauma, and at radiographs, bone density appeared low. Reported pubertal onset was at about 14 years of age (mean age at Tanner stage 2 in Turkish adolescents living in the Netherlands is 12.2 years) (21). He had a somewhat dysmorphic face with mandibular hypoplasia and a prominent forehead. The growth curve is shown in Fig. 2A.

At the age of 16.1 years, dietary calcium and vitamin D intake appeared low, and serum vitamin D25 was slightly decreased, but serum calcium was in the upper normal range and parathyroid hormone (PTH) was normal. Vitamin D p.o. for 6 months resulted in normalization of D25 levels. A grade I mitral and tricuspid insufficiency was detected at cardiologic investigation. The growth hormone (GH) peak after exercise was high (63 mU/l), IGF-I was very low (−6.9 to −5.0 SDS), and IGFBP-3 extremely low (−12.0 SDS). There was a poor response to GH in an IGF-I generation test with two different doses (0.8 and 1.6 mg/m² per day for 4 days); only on the higher dose IGF-I increased from 16 to 60 ng/ml. IGFBP-3 did not change.

At the age of 17.8 years, his bone age was adult, and he had reached a final height of 149.7 cm (−4.2 SDS) (Fig. 2A), indicating a fast progression through puberty, which probably led to the poor pubertal height gain (13.3 cm). At the age of 16, 17, and 19 years, total BMD and z-scores were 0.81 g/cm² (−3.3 SDS), 0.89 g/cm² (−3.9 SDS), and 0.91 g/cm² (−2.5 SDS) respectively, and femoral neck BMD was 0.827 (−1.5 SDS) at 19 years of age.

Patient III-2 moved with his family to the Netherlands at the age of 5 years. At 7 years of age, he was seen by an ophthalmologist because of strabismus. His growth chart is shown in Fig. 2B. Data on reported pubertal onset and progression are inconsistent.

Patient III-4 had a reported birth weight of 2.0 kg at an unknown gestational age. He remained short during childhood and adolescence (Fig. 2C), but bone maturation was not retarded. During infancy, he experienced poor appetite, frequent episodes of diarrhea, and night sweating. His left leg was ~5 cm shorter than the right leg, probably due to congenital coxa vara by congenital femoral hypoplasia. After an osteotomy, the difference was reduced to 3 cm. He had a similar dysmorphic face as patient III-1. Puberty onset was reported to have occurred between 12 and 14 years. Total BMD at 6, 10, and 12 years of age was 0.68 (−1.3 SDS), 0.76 (−1.2 SDS), and 0.62 g/cm² (−2.0 SDS) respectively. The GH peak after exercise was high (118 mU/l), IGF-I was very low (−4.2 to −3.8 SDS), and IGFBP-3 extremely low (≤−17 SDS). During IGF-I generation tests, employing GH doses 0.8 and 1.6 mg/m² per day for 4 days, the IGF-I levels increased only marginally, from 38 to 46 ng/ml and 44 to 52 ng/ml respectively. DNA analysis for GH and GHR was normal.
**Molecular studies**

Sequence analysis of the ALS gene of patients III-1, III-2, and III-4 revealed a homozygous duplication of a T nucleotide at position 1490 of the coding DNA, resulting in a frameshift and a premature stop codon (c.1490dupT, p.Leu497PhefsX40; further indicated as −/−) (Supplementary Fig. 1, which can be viewed online at [http://www.eje-online.org/supplemental/](http://www.eje-online.org/supplemental/)). Five relatives were heterozygous carriers of the mutation (+/−) and the other five non-carriers (+/+) (Fig. 1).

**Clinical, radiological, and biochemical features at recall**

Clinical, radiological, and laboratory findings are summarized in Tables 1–3. Mean height and head circumference SDS of heterozygotes were 1 and 0.7 s.d. lower respectively than those of non-carriers, but the differences with non-carriers did not reach statistical significance (P=0.25 and 0.13 respectively). The sitting height/height ratio was in the upper normal range in most cases, without apparent association with the ALS defect. Two homozygous patients exhibited a low BMD and one of them also a low BMAD, but also in four out of nine relatives low values were observed. Tone audiometry did not show a clinically relevant perceptive hearing loss in the patients or their relatives (data not shown).

In the three patients, ALS was not detected by ELISA, which was confirmed by western blotting of patient’s sera (Supplemental Fig. 2, which can be viewed online at [http://www.eje-online.org/supplemental/](http://www.eje-online.org/supplemental/)). No ALS bands with aberrant molecular weights were detected. Fasting glucose levels were normal (5.3, 4.5, and 4.6 mmol/l), but insulin was slightly elevated (12, 17, and 14 mU/l), indicating mild insulin resistance. Plasma levels of IGFBP-3 were extremely low, and of IGF-I, IGF-II, IGFBP-1, and IGFBP-2 markedly reduced. Plasma IGFBP-4 and IGFBP-6, and serum testosterone, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and free thyroxine (FT4) levels were normal. In heterozygous carriers, plasma ALS and IGFBP-3 were low. In non-carriers, all parameters were normal.

**Neutral gel filtration**

While in normal control serum, most IGF-I (90%) is associated with the 150 kDa complex (Fig. 3A); in the sera of the three ALS-deficient patients there was almost no 150 kDa complex present. The 40–50 kDa fraction (consisting of binary IGF–IGFBP complexes) was markedly elevated and the free $^{125}$I-IGF-I peak was reduced (Fig. 3B). Addition of purified hIGFBP-3 to these sera did not induce the 150 kDa complex formation, while a slightly increased 150 kDa peak was observed upon addition to normal serum (data not shown). Similar results were obtained with $^{125}$I-IGF-II (data not shown). In the sera of heterozygous carriers, the amount of the 150 kDa complexes was reduced and that of the 40–50 kDa complexes markedly increased (Fig. 3C). Column profiles of sera of the non-carriers were normal.

**Discussion**

We report three brothers of Kurdish origin, born from a consanguineous family, with a novel homozygous frameshift mutation in the ALS gene, presenting with short stature and microcephaly. In two cases a low BMD was observed, in one of them twice resulting in a fracture; but further studies of BMD in their relatives

suggest that other genetic factors may be involved. Biochemically, serum ALS was undetectable; IGFBP-3 extremely low: IGFs, IGFBP-2, and IGFBP-1 decreased: and the ternary 150 kDa complex was virtually absent. Most of the circulating IGFs were either sequestered by IGFBPs forming binary complexes or remained unbound. The western blotting experiments indicate that there is no truncated form of ALS present. Even if this were the case, a truncated ALS would not be able to form the stable 3D doughnut-shaped structure, which is essential for its function.

The growth pattern of all previously reported cases of ALS deficiency (10, 15, 16, 18) is characterized by moderate or mild short stature during childhood and adolescence and a normal or slightly decreased adult stature. Our ALS-deficient patients are much shorter in comparison with the reference population, but this may be due to other genetic factors in this highly consanguineous family. The difference between their mean (near) adult height SDS (–4.1 SDS) and that of the five heterozygous carriers (–2.3 SDS) is 1.7 s.d., comparable with earlier reports. Data on head circumference have not

To convert IGF-1 to nmol/l, multiply by 0.131; IGF-II to nmol/l, multiply by 0.134; ALS to nmol/l, multiply by 15.8; IGFBP-1 to nmol/l, multiply by 0.033; IGFBP-2 to nmol/l, multiply by 0.032; IGFBP-3 to nmol/l, multiply by 33.3; IGFBP-4 to nmol/l, multiply by 0.038; and IGFBP-6 to nmol/l, multiply by 0.034.

*Normal range for non-fasting subjects: 24–57 ng IGFBP-1 per ml. After overnight (on) fasting, there is an average fivefold rise in normal individuals. IGFBP-1 SDS values are not available for adults older than 24 years.

been presented in earlier reports; thus it remains to be established whether microcephaly represents a clinical feature of homozygous ALS deficiency.

The growth pattern in humans with ALS deficiency is comparable with the mild growth failure observed in ALS gene knock-out (ALS-KO) mice, and is in contrast with the severe growth failure as observed in patients with a total IGF-I deficiency (2). This is in line with the hypothesis that the contribution of locally produced IGF-I to longitudinal growth is more important than that of IGF-I derived from the circulation (10, 17).

As speculated previously, local production of IGF-I may be even higher than normal due to increased GH secretion, and might thereby compensate, at least in part, for any deficiency of circulating IGF-I (10). Another possible explanation of the near-normal growth, in spite of reduced levels of circulating IGF-I, may include an increase in the IGF-I flux toward the peripheral tissue compartments at the expense of the circulating IGF-I pool that cannot be maintained at normal levels without ALS (17, 29). It is uncertain whether ALS deficiency affects fetal growth.

At present, it is uncertain whether an ALS defect is associated with pubertal delay. Three patients described previously seem to have experienced late onset of puberty (17, 18), but in the other cases puberty was normal. In our index patient III-1, pubertal onset was late, in III-2 unknown, and in III-4 normal. The low BMD in two of our patients and in the first published case (19), in combination with the low BMD in ALS-KO mice (30–32) and previous studies showing that circulating IGF-I levels are related to sufficient bone growth and acquisition of peak bone mass (33, 34), suggested that ALS deficiency might be associated with a low BMD. However, further observations in the patients’ relatives did not support this.

Biochemically, in all cases reported so far, undetectable or very low levels of circulating ALS, extremely low IGFBP-3, and low IGF-I and IGF-II have been reported. The lack of the 150 kDa complex formation is expected to shorten the half-life of IGF-I in the circulation (31), and possibly also that of IGFBP-3 (10). The low IGFBP-1 and IGFBP-2 plasma levels observed in two earlier papers (16, 18) and in our three patients suggest that this is part of the syndrome. A consequence of the low plasma IGFBP-1 (an inhibitor of IGF-I effects) may be that growth is less compromised than would be expected from the low circulating IGF-I levels alone.

In the cases tested, we found an increased GH response to provocative stimuli, confirming earlier observations (10, 16, 18). The increased GH secretion can be explained by the reduction in free IGF-I as observed in previous studies (10, 35, 36), but is in contrast to the normal free IGF-I and GH levels in ALS-KO mice (19, 31). An IGF generation test was performed in three previous cases (10, 16, 18), and showed virtually no response of IGF-I, similar to the two cases tested. Our patients had a mild insulin resistance, confirming earlier reports (16, 18).

Heterozygosity for an ALS defect may have some effect on stature and head circumference compared with non-carriers, but these differences did not reach statistical significance. Within the heterozygous and wild-type individuals, height and head circumference varied considerably, which may be due to other genes that negatively affect growth in this highly consanguineous family. As in most previous reports, parents of affected patients were relatively short (10, 18); a meta-analysis of all cases may shed more light on this issue. Biochemically, carriers had low plasma ALS and IGFBP-3, and IGF-I in the low normal range, as reported previously (10).

In conclusion, these three cases with a novel frameshift mutation of ALS resulting in undetectable circulating ALS levels show that besides short stature...
and possible delayed onset of puberty. Microcephaly may also be part of the syndrome. Biochemically, the absence of circulating ALS leads to extremely low levels of IGFBP-3, very low levels of IGF-I and IGF-II, low plasma IGFBP-1 and IGFBP-2, and mild insulin resistance. Heterozygosity for an ALS defect may have a small effect on height and head circumference.
