CLINICAL STUDY

Long-acting octreotide treatment causes a sustained decrease in ghrelin concentrations but does not affect weight, behaviour and appetite in subjects with Prader–Willi syndrome

Abstract

Objective: Ghrelin is secreted primarily by the stomach and circulates as both acylated and desacyl ghrelin. Acylated (but not desacyl) ghrelin stimulates appetite. Both concentrations are elevated in Prader–Willi syndrome (PWS), suggesting that ghrelin may contribute to hyperphagia and overweight in these subjects. We evaluated whether long-acting octreotide (Oct) decreases acylated and desacyl ghrelin concentrations, body mass, appetite and compulsive behaviour towards food in adolescents with PWS. **Design:** A 56-week prospective, randomized, cross-over trial.

Methods: Nine subjects with PWS (age 14.6 (10.8–18.9) years, body mass index (BMI) Z-score +1.9 (0.6–3.0)) received either Oct (30 mg) or saline i.m. every 4 weeks for 16 weeks and were switched over to the other treatment after a 24-week washout period.

Results: Eight subjects completed the study. Oct caused a decrease in both acylated (–53%) and desacyl (–54%) fasting ghrelin concentrations ($P < 0.05$) but did not significantly affect BMI. Oct had no significant effect on peptide YY concentrations, appetite or compulsive behaviour towards food. Oct caused a decrease in insulin-like growth factor-I concentrations, an increase in HbA1c and transient elevation of blood glucose in two subjects. Three subjects developed gallstones.

Conclusions: Oct treatment caused a prolonged decrease in ghrelin concentrations in adolescents with PWS but did not improve body mass or appetite. Future intervention studies aiming at clarifying the role of ghrelin in PWS should focus on the administration of specific inhibitors of ghrelin secretion or ghrelin receptor activity that do not interfere with other appetite-regulating peptides.

European Journal of Endocrinology 159 381–388

Introduction

Obesity is a cardinal feature of Prader–Willi syndrome (PWS). It is characterized by hyperphagia, persistent hunger with increased caloric intake, decreased perception of satiety and compulsive behaviour that is primarily food related (1, 2). The treatment of obesity in PWS is difficult and requires a comprehensive multidisciplinary approach as well as constant involvement of the parents or caregivers with establishment of rigid structures to limit food intake and promote supervised physical activity.

Ghrelin is a peptide hormone mainly secreted by the stomach. It circulates as acylated and desacyl ghrelin. The presence of an acyl chain on the Ser 3 residue of ghrelin is necessary to activate the growth hormone (GH) secretagogue receptor that mediates the orexigenic

action of ghrelin at the hypothalamic level. Accordingly, exogenous administration of acylated (but not desacyl) ghrelin increases appetite. An inverse correlation has been observed between circulating ghrelin and insulin concentrations, suggesting a role for ghrelin in glucose metabolism (3). In addition, ghrelin concentrations increase with fasting and decrease following a meal (4), suggesting a possible role in meal initiation. The exact role of endogenous ghrelin in humans remains unclear. In adult (5) and young (3, 6) obese subjects (without PWS), ghrelin concentrations are decreased compared with lean subjects suggesting that ghrelin does not play a causal role in the development of obesity. By contrast, subjects with PWS are characterized by elevated ghrelin concentrations despite their weight excess (7), raising the possibility that ghrelin may contribute to the food-seeking behaviour observed in these subjects.

Somatostatin, a hormone that inhibits the secretion of GH, insulin and gut hormones such as the anorexigenic peptide YY (PYY), markedly decreases ghrelin concentrations (8). In addition, repeated administration of a short-acting analogue of somatostatin was also shown to cause a decrease in circulating total ghrelin concentrations for up to 1 week (9). Whether this intervention also affects the acylated form of ghrelin, and whether a longer treatment duration decreases weight gain in these subjects is presently unknown. We hypothesized that therapy with the long-acting form of octreotide (Oct), a somatostatin analogue, would cause a prolonged decrease in ghrelin concentrations in subjects with PWS. The objectives of this pilot study were 1) to determine the effect of Oct treatment for 16 weeks on fasting and on post-glucose load plasma acylated and desacyl ghrelin concentrations and on weight gain, food-seeking behaviour and appetite and 2) to monitor the safety of Oct in subjects with PWS.

Subjects and methods

Design and schedule

Nine subjects (five males and four females) with PWS participated in this 56-week randomized, double-blind, cross-over trial. Inclusion criteria were: diagnosis of PWS confirmed by genetic testing, age >10 years and body mass index (BMI) >85th centile for chronological age. Exclusion criteria were: gallstone on ultrasound or abnormal electrocardiogram (ECG) at baseline, pregnancy, previous use of Sandostatin LAR, medications known to affect food intake, type 2 diabetes, untreated hypothyroidism and severe rectal picking. The subjects were recruited from the endocrinology and genetics clinics at British Columbia Children's Hospital (Vancouver, $n=6$) and Alberta Children's Hospital (Calgary, $n=3$). The subjects were randomized into receiving 4 i.m. injections of 30 mg Oct acetate (Sandostatin LAR, Novartis Pharmaceuticals; Oct phase) or saline (placebo phase, Pla) at 4-week intervals. After a 24-week washout period (1.5 times the time required for complete disappearance of Oct after a single injection (10)), the subjects were switched over to the other treatment modality. In order to ensure proper blinding to the medication (Sandostatin LAR is easily distinguished from saline), injections were performed in the absence of the parents by a nurse who was not otherwise involved in the study. The study was approved by the University of British Columbia Ethics Review Board ('ClinicalTrials.gov' Identifier: NCT00175305). We received consent for participation from the subjects' legal guardians and, when appropriate, assent from the subjects.

Evaluations

There were a total of 10 visits. Anthropometric measurements were performed at each visit. Hormonal

and biochemical investigations, gallbladder ultrasound and nutritional and behavioural studies were performed prior to the first injection and 4 weeks after the last injection of each phase.

Body measurements and laboratory investigations

Height and weight were measured in duplicate in light clothing without shoes. BMI (weight (kg)/height (m)²) and BMI Z-score (using the least mean squares (LMS) method) were calculated (11). Body composition was assessed in both centres by dual-energy X-ray absorptiometry (DXA) using a Hologic QDR 4500 W bone densitometer.

Subjects were admitted between 0800 and 0900 h after a 12-h fast. An oral glucose tolerance test (OGTT) was performed (1.75 g/kg glucose, max 75 g) during which blood was drawn for determination of glycosylated haemoglobin (HbA1c) and insulin-like growth factor-I (IGF-I) (0 min), acylated and total ghrelin, PYY, and insulin and glucose (0 and 120 min) concentrations. In addition, in five subjects, we were able to collect blood samples 30, 60 and 90 min following glucose ingestion. Blood was kept on ice until centrifugation (4 °C) and aliquots of plasma were stored at -80 °C. Ghrelin, PYY, IGF-I and insulin determinations were batched and centralized. For ghrelin determination, 50 µl phenylmethane-sulfonyl fluoride (10 mg/ml solution, Sigma) and 50 µl of 1 M hydrochloric acid were added to each ml plasma immediately following centrifugation. For PYY determination, aprotinin (Trasylol, 10 000 KI/ml, 50 µl/ml plasma; Bayer Inc.) was added to the EDTA tube prior to blood collection. Total (acylated + desacyl; #GHRT-89HK, Linco Research, St Charles, MO, USA) and acylated (#GHRA-88HK, Linco) ghrelin concentrations (12), PYY-like immunoreactivity (PYY3-36 plus PYY1-36) (13) and glucose and insulin concentrations (12) were determined as described previously. Desacyl ghrelin concentrations were calculated by subtraction (total minus acylated). IGF-I was determined by ELISA (DSL-5600, Diagnostic Systems Laboratories, Webster, TX, USA; intraassay coefficient of variation <7.1%). HbA1c was determined in Vancouver by latex immunoagglutination inhibition (DCA 2000+, Bayer Health Care) and in Calgary by immunoturbidimetry (Cobas Integra 700, Roche Diagnostics Corporation). As both assays are part of the National Glycohemoglobin Standardization Program (www.ngsp.org), the results were pooled and analyzed together.

Evaluation of food intake Food intake was assessed through a 3-day food record (Food Processor SQL nutrition and fitness software, ESHA Research, Salem, OR, USA, version 9.7, 2005) completed by the parent (and the subject if appropriate) during the week just prior to the beginning and end of each phase.

Psychometric assessment At four time points, the beginning and end of Pla and Oct phases, subjects and caregiver respondents completed a questionnaire

battery assessing satiation, obsessive and compulsive observations, food-seeking behaviours, maladaptive behaviours (non-food related) and general competencies.

- a. Child Behaviour Checklist (CBCL) for ages 6–18. The CBCL/6-18 is a norm-referenced, diagnostic and statistical manual (DSM)-oriented scale assessing competencies and maladaptive behaviour/problems. Our study focused on the results of the scale's maladaptive behaviour component, a 118 item forced choice index of internalizing behaviours such as being anxious or withdrawn, externalizing behaviours such as rule breaking and aggression, and total problems, a combination of internalizing and externalizing problems in addition to social, thought and attention problems (rev in (14)).
- b. Child Yale-Brown Obsessive Compulsive Scale (CY-BOCS). The CY-BOCS measures the severity and cluster type of compulsive behaviours and obsessive thoughts in subjects with obsessive–compulsive disorder (15). Compulsions and obsessions are organized into nine common clusters such as washing/cleaning and somatic problems. Questions demanding a high degree of self-awareness, i.e. those pertaining to control exerted over compulsive behaviour or degree of insight into obsessions and compulsions, were removed from our study due to caregiver informant versus subject responders.
- c. Feeding Behaviour Questionnaire for PWS. We used a modified version of the Eating Disorders Examination questionnaire (16) developed by DeSantadina and Berall (University of Toronto, personal communication). The scale is a 14 item forced choice questionnaire assessing the presence and degree of maladaptive food-seeking behaviour; it is directed to parents/guardians. The modified questionnaire contains additional items on nausea.
- d. Visual Analogue Scale (VAS). Evaluation of hunger was performed using a previously validated VAS for children with PWS (17). Four thermometer graphics displaying a temperature gradient corresponding to the intent/direction of the response were added to aid subjects with comprehension of the VAS. Questions include, 'How hungry do you feel?' 'How full do you feel' and 'How much food do you think you could eat?'.

Statistical analysis

Baseline data are expressed as mean (95% confidence interval (CI)) or median (range). The test for order effect of the randomization (Oct or Pla in the first phase) showed that order did not affect the results and all data from each treatment group were therefore combined. Data were analyzed by comparing the changes that occurred in each group (Pla or Oct) during

the intervention. For hormonal data (ghrelin, PYY, insulin and IGF-I), statistical analyses were performed using non-parametric tests for two (Wilcoxon test) or more (Friedman test) related samples. When more than two related samples were present, *post hoc* analysis was performed using Wilcoxon with Bonferroni correction. All other data were normally distributed and we performed paired *t*-tests (two samples) or ANOVA for repeated measures (more than two samples) followed by *post hoc* analysis using paired *t*-test. The relationship between the variables under study was assessed using the Pearson's coefficient of correlation *r*. *P* value <0.05 was considered significant. Data were analyzed with SPSS version 15.0 (2006, SPSS Inc., Chicago, IL, USA).

Results

Baseline characteristics of the subjects

The baseline characteristics of the subjects are reported in Table 1. One subject was included despite a BMI on the 74th centile because of severe food-seeking behaviour and major weight control difficulties. Six patients had a deletion on chromosome 15 and 3, a uniparental disomy. One subject dropped out at the beginning of the second phase, after receiving the first Oct injection, because of acute psychosis. Her baseline determinations are included in Table 1 but her results have otherwise not been analysed. None of the subjects had experienced spontaneous pubertal development. Four male subjects were on a stable dose of testosterone enanthate (range: 25–250 mg/month). One subject had been receiving human GH (0.15 mg/kg per week)

Table 1 Baseline characteristics of the subjects.

	Mean	95% Confidence interval
Age (years)	14.6	10.8–18.9
Height (cm)	147.1	132.2–162.9
Weight (kg)	68.3	45.6–98.4
BMI (kg/m ²)	31.8	23.2–51.0
BMI Z-score	1.9	0.6–3.0
Fat mass (kg)	30.0	18.0–47.1
Body fat (%)	43.4	35.8–52.9
Fasting blood glucose (mg/dl)	88	74–103
2-h blood glucose (mg/dl)	105	77–160
HbA1c (%)	5.1	4.5–5.8
	Median	Range
Fasting acylated ghrelin (pg/ml)	114	39–340
Fasting desacyl ghrelin (pg/ml)	1327	792–2118
Fasting peptide YY (pmol/l)	23.1	15.7–45.6

Fasting IGF-I (ng/ml) ^a	254	177–569

Ghrelin: pg/ml × 0.296 = pmol/l. Peptide YY (PYY): pg/ml × 0.25 = pmol/l. IGF-I: ng/ml × 0.13 = nmol/l. Glucose: mg/dl × 0.056 = mmol/l. Insulin: μU/ml × 6.9 = pmol/l.

^aExcluding one subject on a stable dose of GH.

for 4 years while another started GH therapy 1 month prior to final evaluation (0.3 mg/kg per week). One subject was on a stable dose of L-thyroxin (75 µg/day).

Ghrelin, PYY and glucose homeostasis

Acylated ghrelin represented $13 \pm 4\%$ of total ghrelin concentrations. There was a negative correlation between total ghrelin concentrations and BMI Z-score ($r = -0.77$, 95% CI: 0.21–0.95, $P = 0.016$). Compared with the Pla phase, Oct caused a marked decrease in fasting and 2-h post-glucose acylated ghrelin concentrations in all subjects and a decrease in fasting desacyl ghrelin concentrations in all but one subject. By contrast, Oct did not significantly affect fasting and 2-h post-glucose PYY concentrations (Table 2).

Fasting and 2-h blood glucose tended to increase more in the Oct compared with the Pla phase. Glycosylated haemoglobin decreased slightly during the Pla phase and increased in the Oct phase (Table 2). Two subjects (including one with glucose intolerance at screening) had a 2-h glucose value > 11 mmol/l at the end of the Oct phase but this was resolved following Oct discontinuation.

In the five subjects in whom plasma samples were collected at regular intervals during the OGTT, Oct was associated with a loss of the physiological postprandial decrease in desacyl ghrelin. The change in desacyl ghrelin between 0 (fasting) and 30 min following

glucose intake remained unchanged throughout the Pla phase. By contrast, during the Oct phase, this change went from -294 (-209 to -409) pg/ml at the beginning to $+7$ (-37 to $+46$) pg/ml following four injections of Oct ($P = 0.043$). There was no significant increase in PYY following glucose intake. Oct caused a significant decrease in 0 (fasting) to 30 min (peak) insulin response ($P = 0.008$).

Weight, height, BMI, IGF-I and body composition

Weight increased similarly during each phase ($P = 0.048$ from the beginning to end of the phase). Oct had no significant effect on weight, BMI or % body fat (Table 2 and Fig. 1). There was no significant correlation between the magnitude of the ghrelin response to Oct (whether expressed as absolute changes in ghrelin concentrations or as percentage of the baseline concentrations) and weight or BMI changes. IGF-I concentrations decreased during the Oct compared with the Pla phase.

Behaviour

ANOVA for the various questionnaires assessing the changes in behavioural aspects of the subjects did not

Values represent the changes in a given variable from the beginning to the end of each phase (placebo or octreotide). For statistics, see 'Statistical analysis' section.

^aExcluding one subject who started GH 1 month prior to the end of the Pla phase.

show any significant effect of the intervention. Similarly, visual examination of the individual responses did not show any specific pattern consistent with an effect of the intervention (Fig. 2).

Nutrition

The intervention had no significant effect on the quantitative and qualitative composition of the diet. At baseline, mean (95% CI) reported caloric intake was

1445 (869–1892) cal, with 60 (49–64) % carbohydrates, 20 (15–27) % protein and 20 (9–33) % fat.

Gallbladder ultrasound

Three subjects developed asymptomatic gallbladder abnormalities on the ultrasound by the end of the Oct phase and two of these required cholecystectomy 12–24 months after Oct discontinuation.

Figure 1 Individual values for body weight, BMI and % body fat at baseline and at the end of the Pla and Oct phases in subjects with PWS. The arrow indicates the subject who started GH 1 month prior to the end of the Pla phase.

Figure 2 Individual values for the Child Behaviour Checklist (CBCL total score), feeding behaviour (Eating Disorders Examination questionnaire) and Visual Analogue Scale (VAS).

Discussion

Medical care of adolescents with PWS is complicated and requires a multidisciplinary approach (18). Controlling the hyperphagia and weight excess associated with this condition remains one of the most difficult challenges of the intervention. The elevated total (7) and acylated (19) ghrelin concentrations observed in PWS contrast with the low values found in obese, non-PWS subjects and led us to hypothesize that suppression of ghrelin using long-acting analogues of somatostatin could provide an etiological treatment for the hyperphagia characteristic of PWS and contribute to the care of these subjects. This study demonstrates that Oct successfully decreased fasting and postprandial concentrations of both acylated and desacyl ghrelin for 16 weeks in these subjects. For unclear reasons, one subject failed to show a decrease in desacyl ghrelin (but not in acyl ghrelin). Contrasting with the changes in ghrelin, there were no changes in body weight, body composition, appetite or behaviour towards food.

In adult subjects with PWS, Oct infusion was associated with a 60% decrease in total ghrelin concentrations that were not associated with a decrease in appetite over a single meal (20). Using the dose of 5 µg short-acting Oct/kg body weight, s.c., three times a day for 1 week, Haqq *et al.* (9) observed a 67% decrease in ghrelin concentrations. Using a similar dose given as one injection every 4 weeks, our study is the first to investigate the effect of long-acting Oct on ghrelin in young subjects with PWS.

There are several potential explanations for our results. First, our study included a small number of subjects. As a consequence, despite the use of a cross-over design, we could have missed modest decreases in weight or food intake. However, in contrast to non-specific interventions characteristic of most obesity trials, this study had a specific target: excess ghrelin. If our hypothesis that ghrelin causes hyperphagia in PWS had been verified, we would have expected changes in food intake and behaviour that would be easily noticed, similar to the large and rapid changes observed in leptin-deficient subjects following leptin replacement (21). Second, the decrease in circulating ghrelin, known to mediate appetite regulation, could be too small to be perceived at the hypothalamic level and translate into clinically relevant effects. However, we did not observe a significant correlation between the degree of ghrelin suppression and the changes in weight. Third, Oct blunted the postprandial decrease in ghrelin concentrations, known to be associated with changes in appetite (22). Fourth, the increase in circulating ghrelin reported in PWS may not be present centrally or may not explain the abnormal hunger perceptions seen in these subjects (23). The gene encoding ghrelin is located on chromosome 3 in humans (7) while PWS is associated with the functional loss of paternally expressed genes located on chromosome 15 or

uniparental disomy for maternal chromosome 15 (1). Whether these affected genes are part of a pathway-regulating ghrelin expression remains to be demonstrated. Alternately, increased appetite may be secondary to abnormal expression of non-ghrelin genes. For instance, it has recently been suggested that genes involved in the development of serotonergic pathways are affected in PWS, which could potentially influence appetite (24, 25). Finally, while Oct decreases plasma concentrations of ghrelin, an orexigenic hormone, it also decreases the concentrations of anorexigenic hormones, such as insulin (26) and PYY (27). Because PYY regulation was previously shown to be abnormal in PWS (28), we focused on PYY, which increases rapidly in the circulation in response to a meal to signal satiety (3). In keeping with others, we observed a blunted PYY response to caloric intake in subjects with PWS (29), which could cause an overall decrease in satiety. In contrast to Tan *et al.* (20) who investigated adult subjects with PWS, we found no effect of Oct on PYY concentrations, suggesting that in our study, suppressed PYY concentrations were not an explanation for the lack of effect of Oct on appetite.

Oct treatment is associated with known side effects (30). Prolonged Oct treatment decreases insulin secretion and causes impaired glucose tolerance. Our results showed that Oct increased HbA1c and suppressed insulin response. In addition, two subjects developed blood glucose concentrations in the diabetic range following Oct. Discontinuation of Oct was followed by a normalization of the glycemia. Oct also causes a reduction in bile production and gallbladder contractility with increases in the risk of cholesterol gallstones. In children with hypothalamic obesity, long-acting Oct at the dose of 40 mg every month for 6 months was associated with bile sludge and/or gallstones in 37% of the subjects (31). In our study, gallbladder abnormalities were also present in 37% of subjects after only 16 weeks of treatment at a lower dose and two subjects underwent a cholecystectomy several months after Oct discontinuation. The absence of an obvious weight loss effect and the presence of significant complications observed in this pilot study do not point towards a positive risk benefit ratio for Oct in subjects with PWS.

We used a cross-over design to evaluate the effect of Oct on ghrelin, body mass, behaviour and safety in our subjects. This design has limitations. For instance, the drop out of one subject at the beginning of the second phase made it impossible to analyse any of the data pertaining to this subject. However, it also has advantages that were felt to be very important in our setting. Firstly, a design where each subject serves as his/her own control and receives the placebo/drug in random order makes it possible to obtain meaningful results with a smaller number of subjects despite large inter-individual variations in ghrelin concentrations.

Secondly, this was the first time that long-acting Oct was administered in subjects with PWS and we felt that, from a safety point of view, it was important to expose as few subjects as possible in this pilot study. A parallel design would have required the inclusion of a larger number of subjects.

In conclusion, sustained decreases in acylated and desacyl ghrelin concentrations for 16 weeks following Oct administration did not affect weight, appetite or compulsive behaviour towards food in subjects with PWS. While this does not completely rule out a role for ghrelin in the pathophysiology of appetite in PWS, future intervention studies should aim at clarifying the role of ghrelin and focus on the administration of agents that specifically inhibit ghrelin secretion or its action at the receptor level, do not interfere with other appetite-regulating peptides, and are well tolerated.

Declaration of interest

The authors declare that there is no conflict of interest that would prejudice the impartiality of this scientific work.

Funding

The study was supported by a grant from the Prader–Willi Syndrome Association (USA). Sandostatin LAR® was a gift from Novartis Canada.

Acknowledgements

Kathleen De Waele was the recipient of an ESPE clinical research Fellowship (Novo Nordisk). We would like to acknowledge the team at the Center for Hip Health and Musculoskeletal Research, Vancouver Coastal Health Research Institute for acquiring the DXA scans. Our thanks also go to Dr Elizabeth Mickelson for helpful discussions, to Mabel Tan and Anne Gregnier (Vancouver) and Wendy Schwarz and Laura Kaminsky (Calgary) for their help in assessing the subjects and to Christine Lovatt, Nutritional Analyst. We wish to thank all subjects and their families for their participation.
