Abstract

Context: Recently, in a 4-month proof-of-concept trial, beneficial metabolic effects were reported in non-diabetic children with Berardinelli–Seip congenital lipodystrophy (BSCL); this information prompted us to hypothesize that long-term leptin-replacement therapy might improve or reverse the early complications of the disease in these patients.

Patients and methods: A 28-month trial was implemented in eight patients. Efficacy assessment was based on a decrease in serum triglyceride concentrations, and/or a decrease in liver volume and/or an increase in insulin sensitivity of at least 30% respectively. The response was defined as follows: total (3/3 positive criteria), partial (1 or 2/3), or negative (0/3). Anti-leptin antibodies were measured with a radio-binding assay, and a neutralizing effect was assessed in primary cultures of embryonic neurons incubated with an apoptotic agent (N-methyl-D-aspartate) and the patient serum, with or without leptin.

Results: A negative or partial response to treatment was observed in five of eight patients even when leptin dosages were increased. A displaceable leptin binding was detectable in all patients after 2 months of treatment. At 28 months, binding was higher in the patients with a negative response than in the total responders, and it paralleled both the increase in leptin dosage and serum leptin concentrations. Co-incubation of embryonic neurons with serum from two patients with a negative response inhibited the neuroprotective effect of leptin.

Conclusion: Under leptin therapy, patients with BSCL may develop a resistance to leptin, which could be partly of immunological origin, blunting the previously reported beneficial effects.

European Journal of Endocrinology 162 1083–1091

Introduction

Berardinelli–Seip congenital lipodystrophy (BSCL) is a rare but very severe congenital syndrome characterized by the lack of adipose tissue (1, 2). It is a genetically heterogeneous disorder with an autosomal recessive inheritance for which three genes encoding proteins expressed in the adipocyte, and playing a role in lipid metabolism, have been identified (3–6). Patients with BSCL have high circulating concentrations of triglycerides and develop ectopic fat deposits leading to severe complications early in life. Hepatic storage promotes steatosis and fibrosis and later cirrhosis. Insulin resistance is observed very early in life in these patients, progressing ineluctably toward diabetes which appears around or even before puberty (7). Additionally, dyslipidemia favors arteriosclerosis and cardiovascular diseases, and can affect other organs such as the pancreas where hypertriglyceridemia can cause acute pancreatitis. The prognosis of the disease is very poor, and patients often die in the third decade of life. Treatment is not standardized, is only based on symptoms or complications presented by the patients, and is only able to delay the progression of the disease.

As a direct consequence of the lack of adipose tissue, these patients show nearly undetectable circulating concentrations of leptin, an adipokine which plays a key role in energy regulation through both central and peripheral mechanisms (8–12). The production of recombinant human leptin has provided the opportunity to determine whether leptin-replacement therapy would improve the extremely severe metabolic
derangement found in these patients (13, 14). Following two trials in adults, we have reported previously that leptin was able to reduce or even correct insulin resistance, dyslipidemia, and hepatomegaly in five of seven patients after 4 months of therapy (15). However, full reversal cannot be attained in all patients in such a short period of time since up to 1 year of treatment has been reported as being necessary for the improvement of hormonal, metabolic, and immune disorders in some adults with lipodystrophy (13). Moreover, if the benefits of leptin replacement can be sustained on a long-term basis, this treatment would represent the first opportunity to reduce the progression of the severe metabolic complications by blocking ectopic fat storage in children with BSCL. However, long-term data (≥1 year) are only available in a few reports (13, 14). The aim of this second trial in children with BSCL was to assess the long-term efficacy and safety of leptin-replacement therapy to correct for the metabolic disorders.

Research design and methods

Patients

Eight patients (two girls and six boys, Tanner stage between I and IV) were enrolled in the study. Inclusion criteria were genetically assessed diagnosis of BSCL, low leptin concentrations (<3 ng/ml), and at least one abnormal feature (hyperinsulinemia >15 mUI/l and/or triglyceride concentration >2 mmol/l). Characteristics at enrollment are given in Table 1. Seven patients (patients 1–7) were previously enrolled in the first 4-month trial (15), and the time between the two studies was ~18 months.

Study design

The study was a prospective, open-labeled, non-randomized phase II trial. Children were kept on their recommended diets for the duration of the trial (low-lipid diet: 20% of daily caloric intake, medium-chain fatty acid supplementation). Informed written consent was obtained from all subjects and from their families. The Paris/St-Louis ethics committee approved the protocol. Criteria for a positive response to treatment were defined as a reduction in liver volume of at least 30% and/or a 30% improvement in insulin sensitivity and/or a 30% of fasting triglycerides. These criteria were similar to those of the first trial and were the ones used in the NHI trial. Patients showing improvement in the three criteria were considered as total responders, and those with improvement in one or two criteria were considered as partial responders and lack of improvement in any of the criteria was defined as a negative response.

Leptin administration

Recombinant methionyl human leptin was provided by Amylin Inc. (San Diego, CA, USA). Leptin was administered subcutaneously once a day. The dosage was progressively increased over the first 2 months to achieve a dosage of 0.06 mg/kg per day, which was maintained throughout the first year. At the end of the first year, the dosage was increased to 0.09 or 0.12 mg/kg per day in the children who showed either a partial or no response respectively. At the time of evaluation, the total duration of leptin-replacement therapy was 28 months in all patients, and the dosage was 0.06 mg/kg per day in one patient, 0.09 mg/kg per day in four patients, and 0.12 mg/kg per day in three patients (Table 2).

Procedures

Blood lipids, insulin sensitivity, energy expenditure, and liver enzymes were measured every 4 months during a 48-h hospitalization in the Clinical Investigation Unit at Robert Debre Hospital in Paris. Body composition and liver volume were measured at enrollment, month 12 and month 28. Blood lipids were measured on a single sample before the clamp and following an overnight fasting preceded by a standardized dinner.

Blood fat and whole body bone mineral density were determined by dual-energy X-ray absorptiometry (DEXA, Lunar Prodigy DXP Pro, GE Medical Systems, Madison, WI, USA). Liver volume was calculated using computed tomography (CT) scanning applying a standardized procedure with measurements of height, width, and length (accurate to 0.1 cm). Respiratory quotient and resting energy expenditure were determined by indirect calorimetry using a QUARK PFT (Cosmed, Roma, Italy), which was performed before the euglycemic–hyperinsulinemic clamp after an overnight fast. Children were kept in bed and remained quiet while watching television. Respiratory gas exchange was continuously monitored for 10 min using a ventilated hood. The measurements obtained between the first and the fifth minute were discarded to allow the children to get accustomed to the procedure. Energy expenditure was calculated using the equations of Livesey et al. (16).

Insulin sensitivity was measured as the peripheral glucose uptake (M) at steady state of a 120-min euglycemic–hyperinsulinemic clamp (17). Insulin was infused throughout the test at 40 mUI/m² per min. Peripheral glucose uptake was calculated as the average glucose infusion rate (plus hepatic glucose output (HGO)) at a steady state over two consecutive 20-min periods, and was corrected for mean plasma glucose concentrations and fat-free mass. Glucose turnover rate was determined by the tracer dilution method utilizing [2H]-glucose. HGO was calculated at baseline and at the steady state of the euglycemic clamp. In one young

patient (patient 4), insulin sensitivity was assessed by calculating parameters derived from the glucose tolerance test. Quantitative insulin sensitivity check index (QUICKI) was calculated as follows: \( \text{QUICKI} = \frac{1}{\log \text{fasting insulin} - \log \text{fasting glucose}} \).

**Biochemical analyses**

Plasma glucose concentrations during the clamp were measured by the glucose oxidase method on an on-site GM9-glucose analyzer (Analox, London, UK). Serum insulin concentrations were measured using an IRMA (Bi-Insulin IRMA, Cis Bio, Bagnols/Cèze, France). Alanine transaminase, aspartate transaminase, \( \gamma \)-glutamyltransferase, and alkaline phosphatase were determined by enzymatic methods using an ADVIA analyzer (Siemens, Bayer Diagnostics). Triglycerides and total cholesterol were determined according to the standard methods with the use of automated equipment. HbAlc levels were measured by ion exchange HPLC. Serum leptin concentrations were measured 24 h after the last injection using a specific RIA (Linco Research, St Charles, MO, USA). Sensitivity of the leptin assay is 0.4 ng/ml. Intra- and inter-assay coefficients of variation are 5.2 and 8.7% respectively at 2.3 ng/ml.

**Assessment of leptin antibodies**

Anti-leptin antibodies were measured in serum samples using a sensitive radioassay preceded by dextran–charcoal extraction of serum leptin. Briefly, 200 μl of serum were mixed by gentle stirring with 250 μl of 0.085 M HCl and 100 μl of dextran–charcoal suspension. After centrifugation, 80 μl of supernatant were

Hepatic volume: + = reduction in liver volume ≥30% between month 0 and month M, insulin sensitivity: + = ≥30% increase in insulin sensitivity between month 0 and month M, triglycerides ≥30% reduction of fasting triglycerides between month and month M.

**Table 2** Response to leptin-replacement treatment at months 4, 12, and 28.
incubated with 20,000 c.p.m. of $^{125}$I-iodine-labeled leptin (Linco Research), with or without the addition of 2.5 ng of cold human leptin. Polyethylene glycol (1.5 ml, PEG) solution in buffer (15%, v/v) was added to the tubes, which after 20 min were centrifuged and counted in a gamma counter after aspiration of the supernatant. In control sera, the bound radioactivity (mean ± S.D.) was 4.8 ± 0.7% before the addition of cold leptin, and 4.3 ± 0.5 after displacement of bound radioactive leptin by cold leptin (difference 0.53 ± 0.29%). A sample was considered positive for the presence of anti-leptin antibodies when the percent binding was > 6.9% of total radioactivity (mean of controls + 3 S.D.), and the difference between binding before displacement and after displacement was > 1.5% of total radioactivity (control mean displacement + 3 S.D).

Neutralizing antibodies

Cerebral cortices taken from embryonic mice at 14 days of gestational age were dissected free from the meninges in HEPES-buffered Hank’s solution (HBSS, Gibco). Brain tissue was dissociated first enzymatically (0.25% trypsin in HEPES-buffered Hank’s solution (HBSS, Gibco). Brain of gestational age were dissected free from the meninges. Cerebral cortices taken from embryonic mice at 14 days in HBSS followed by DNase digestion), and then mechanically (20–30 passages through a Pasteur pipette). Cells were resuspended in Eagle’s minimum essential medium (Sigma) containing 10% horse serum, 2 mM glutamine, and 33 mM glucose, and were plated on 12-mm coverslips coated with poly-DL-ornithine (Sigma). Cultures were kept at 37 °C in a humidified CO₂-containing atmosphere. After 2–4 h, the medium was replaced by Neurobasal medium supplemented with B27 (Life Technologies). On the fifth culture day, one-third of the plating medium was changed, and 5 μM cytosine arabinoside was added to halt non-neuronal cell division. Nine- to 11-day-old mature neuronal cultures that displayed extensive axonal networks and were almost devoid of glial cells were exposed for 20 h to 10 ng/ml recombinant mouse leptin (R&D Systems Europe, Lille, France) alone, or in combination with either 100 μg/ml neutralizing anti-leptin antibody (R&D Systems) or 10 μg/ml serum from human controls or from patients.

Results

Metabolic response to substitutive therapy

At enrollment, all patients had nearly no measurable body fat or circulating concentrations of leptin. Despite their restricted diet, six of eight patients demonstrated fasting hypertriglyceridemia (Table 1 and Fig. 1A). Mean (± S.D.) total and high density lipoprotein (HDL) cholesterol were 3.9 ± 1.8 and 0.84 ± 0.16 mmol/l respectively. All patients had marked to extreme hepatomegaly as measured by CT scan (Fig. 1C). In five of seven patients, the ratio of hepatic to splenic CT attenuation was under 0.95, indicating that fat accumulation was in the liver. Hepatic enzymes were increased in five patients (Table 1). Before therapy, all patients showed elevated fasting insulin (30.6 ± 13.4 mIU/l) suggesting a marked degree of insulin resistance, which was confirmed by their very low glucose uptake (between 0.43 and 5.6 mg/kg per min) at steady state during the euglycemic–hyperinsulinemic clamp (Fig. 1B). Only one patient (patient 5) had overt diabetes with very high HbA1c levels (Table 1).

Changes in triglyceride concentrations, insulin sensitivity, and liver volume are shown in Fig. 1A–C, with response patterns over the whole trial being summarized in Table 2. Characteristics of the patients at 28 months of therapy are given in Table 1.

During treatment, residual serum leptin concentrations increased, and were sustained within the physiological to supraphysiological ranges (from 1.85 ± 0.01 ng/ml at M0 to 238.2 ± 519 mg/ml at M28, P = 0.008). Simultaneously, patients with a total or partial response to treatment showed a transient reduction in appetite, but this effect was attenuated after 6–12 months of therapy and was not associated with either changes in resting respiratory quotient (from 0.78 ± 0.03 to 0.8 ± 0.06, NS) or changes in resting energy expenditure (from 39.86 ± 11.56 to 45.6 ± 17.1 kcal/kg per mn. NS). Leptin neither induced
earlier puberty in the prepubertal children nor corrected amenorrhea of patient 5 nor changed bone density z-score (from 2.06 ± 1.07 to 2.13 ± 1.1 s.d., NS).

Serum triglyceride concentrations returned to physiological values in four patients (patients 2, 3, 6, and 7) within the first 4 months of treatment and in one more patient (patient 4) at the end of the first year (Fig. 1A). Four of these patients maintained normal fasting triglyceride concentrations until month 28, while dyslipidemia reappeared at the end of the first year in patient 6 and could not be corrected by increasing the dosage. Triglyceride concentrations remained elevated throughout the trial in patients 1, 5, and 8. HDL cholesterol levels did not change over the course of the 28 months (from 0.84 ± 0.16 to 0.85 ± 0.2 mmol/l, NS) in all patients.

Patients 2, 3, and 7 showed an improvement in insulin sensitivity, the values of which returned to physiological levels (Fig. 1B). Patient 6 only showed a transient improvement during the first 4 months of the trial, while insulin resistance reappeared at the end of the first year and could only be corrected by increasing the dosage. By contrast, there was no improvement in insulin sensitivity in patient 4. Patients 1, 5, and 8 showed a marked aggravation of insulin resistance. Patient 5 showed a dramatic deterioration in the metabolic control of diabetes with HbAlc reaching 12.2% at 28 months. Similarly, patient 8 developed severe clinical diabetes under leptin therapy at the maximal dosage.

Five patients demonstrated an improvement in liver volume (patients 2, 3, 4, 6, and 7; Fig. 1C) with a decrease in the ratio of hepatic to splenic CT scan attenuation (>0.00.95) indicating reduction of hepatic steatosis.

Altogether, after 28 months of therapy, a total response was observed in only three patients, with the leptin dose being increased up to 0.09 mg/kg per day in two of these patients (Table 2). Two other patients demonstrated a partial response with the same dosage. The remaining three patients demonstrated a negative response at 28 months of therapy with the maximal dosage of leptin, whereas glycemic control was not improved in the two diabetic patients.

**Assessment and characterization of antibodies against recombinant leptin**

In an attempt to explain the total or partial resistance to the metabolic effects of leptin, we postulated the formation of anti-leptin antibodies triggered by the administration of the peptidic hormone. An in-house assay was developed to specifically detect these antibodies. At the beginning of the second trial, leptin binding to molecules precipitated by PEG was detectable in the seven patients who had previously been enrolled in the first 4-month trial, and which was followed by a washout period of 18 months. This percentage of binding was lowest in the patients who were later total responders (7.6, 10.1, and 9.1% respectively in patients 2, 3, and 7), and by contrast, the highest (29.9 and 17%) occurred in non-responding patients.

After 28 months in the second trial, binding increased in all patients, but it increased more dramatically in patients with a negative response than in patients with a total response (Fig. 2). The molecular weight of the binding molecules as assessed by gel filtration was found to be close to 150 kDa, a value consistent with that of a leptin–antibody complex.

In order to further investigate the neutralizing effect of these antibodies, we used an in vitro assay that was previously used to demonstrate the neuroprotective effect of leptin to NMDA exposure in embryonic neurons in primary culture. Even if looking at the neuroprotective effects may not be relevant with respect to the metabolic effects of leptin, the former involves part of the
classical intracellular signaling pathway in the response of leptin binding to its receptor and could then be used to demonstrate the neutralizing effect of antibodies on the leptin signaling pathway. In the NMDA-treated culture, cell death reached 40%, but was decreased to 20% when the culture was co-treated with leptin (Fig. 3). The addition of a commercial neutralizing antibody led to a similar number of apoptotic cells that reported with NMDA culture alone (Fig. 3). At the commencement of the second trial, NMDA-treated cells were co-incubated in the presence of serum from two patients who later showed a negative response (serum from patient 5: binding = 18% and serum from patient 8: binding = 7.2%) with or without leptin. As shown in Fig. 3, leptin still induced a decrease in the number of apoptotic cells. By contrast, addition of serum from the same patients at month 28 of therapy (45% of binding in patient 5 and 94% of binding in patient 8) inhibited the neuroprotective effect of leptin, demonstrating the neutralizing effect of antibodies in this situation. Furthermore, the residual leptin concentrations were low in patients with a total response despite the presence of antibodies. The higher residual concentrations in patients with a negative response were associated with higher binding, suggestive of a trapping effect of leptin.

Discussion

In this 28-month trial of children with BSCL, the majority of the patients developed a partial or total resistance to the metabolic effects of the recombinant leptin despite a significant progressive increase in the leptin dosage. The need for an increasing dosage to maintain the metabolic effects of leptin has been reported in other trials, such as those in children with congenital leptin deficiency (18–20). However, in the present trial, even the high doses of leptin failed to improve glycemic control or antidiabetic agent dosage requirements in the two diabetic patients, which is in clear contrast to the results from previous trials reported in the literature (13, 14). This pattern of ‘resistance’ to a peptidic hormone prompted us to postulate a possible immune mechanism responsible for such ‘leptin resistance’. The occurrence of antibodies in patients undergoing leptin-substitutive treatment has been reported in children with congenital leptin (19) deficiency, but it is poorly documented in BSCL. Antibodies were not mentioned in the American trial conducted in lipodystrophic adults (13), and antibodies reported in Japanese patients were not characterized as neutralizing (14). We demonstrated, in vitro, a neutralizing effect of the sera of two patients on the neuroprotective effect of leptin in primary culture of embryonic neurons (21). Upon retrospective analysis, we found that these antibodies appeared early, during the first 4-month trial after the end of the first month of leptin administration, and further increased thereafter.

The appearance of antibodies following a substitutive hormonal therapy has been reported with other recombinant proteins (22–27), and it can suggest some mechanisms for the resistance reported here. In type 1 diabetic patients, the production of antibodies against insulin is common but without reported clinical
relevance, and has been observed with bovine, porcine, and recombinant insulin (25–27). Antibody production interfering with the treatment effect has been well documented in children with congenital GH deficiency (22–24). In some cases, this resistance seemed to be linked to the change in the amino acid sequence of the recombinant protein (28).

As reported in animal models of congenital leptin deficiency, the transient beneficial effects that we reported previously in these patients could be linked to transitory effects on satiety regulation leading to a decrease in nutritional intake and then to circulating lipids (29). In humans, some data are available on the effects of leptin-substitutive therapy on neuronal activation in key striatal regions in patients with congenital leptin deficiency: these data suggest that the recombinant hormone acts on neural circuits governing food intake to diminish the perception of food reward while enhancing the response to satiety signals generated during food consumption (30). Such effects would appear rapidly (in the first 2 weeks) after the beginning of leptin therapy (30). Here, we have demonstrated in vitro that antibodies produced by some patients canceled out the biological effect of leptin on embryonic neurons. If the biological effect investigated in vitro is not the one of appetite control, we can suggest that the lack of clinical effect that we reported in this second trial could be at least partly linked to a lack of central effects of the therapy. We did not record calorie intake, but parents constantly reported increased satiety over the first few months of therapy. This effect rapidly disappeared in patients with a negative response and was attenuated after some months of therapy in other patients, only re-appearing in the weeks following the increase in dosage. However, we did not observe changes in resting energy expenditure, which is not in keeping with an effect on neuronal pathways controlling energy expenditure. Interestingly, the only effect that was maintained over time in our patients – but at the price of increasing the dosage of leptin – was the reduction of hepatic steatosis, arguing for an additional peripheral effect of the molecule (31).

Therefore, we report here that some lipodystrophic patients developed a resistance to leptin-substitutive therapy blunting the beneficial effects we reported previously. This resistance could be mediated, at least in some patients, through an immunological process with severe clinical consequences since therapeutic alternatives in these patients are poor and ineffective in inhibiting the life-threatening prognosis of the disease.

Declaration of interest

Funding

This work was supported by a grant from the COSSEC/Institut National de la Santé et de la Recherche Médicale (INSERM). J Beltrand was supported by a grant from INSERM (Poste d’accueil, 2007). N Lahhou was partly supported by a grant from Institut de Recherche Endocrinienne et Métabolique (Paris, France). The funders had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Acknowledgements

The authors are grateful to the nursing staff of the Clinical Investigation Centre (CIC-9202) of Robert Debré Hospital and Miss Lila Benadjoud. They acknowledge the skilful technical assistance of Mr François Luc (CIC-9202) and Ms Leslie Schwendimann (INSERM U676).
