Abstract

Objective: Primary hyperparathyroidism (PHPT) is associated with cardiovascular morbidity. The extent of cardiovascular abnormalities in patients with mild-asymptomatic disease is unclear. Using sensitive echocardiographic methods, we compared cardiac structure and function in patients with mild PHPT and in healthy controls, and evaluated the changes after parathyroidectomy (PTX).

Methods: In a prospective case-control design, we studied 51 PHPT patients without any cardiovascular risk factors/diseases and 51 healthy matched controls. Cardiac structure, and systolic and diastolic function were evaluated by echocardiography and Doppler tissue imaging (DTI). Blood pressure (BP) and heart rate were measured.

Results: We observed no differences in systolic or diastolic function or in cardiac morphology between the PHPT patients and the age-matched healthy controls. The regional peak systolic myocardial velocities (S') measured with DTI decreased at all sites ($P < 0.05$) after PTX (tricuspid annulus 14.23 ± 1.85 to 13.48 ± 1.79 , septal 8.48 ± 0.96 to 7.97 ± 0.85 , and lateral 9.61 ± 2.05 to 8.87 ± 1.63 cm/s, part of the mitral annulus). At baseline, systolic BP was higher in patients compared to controls (127.6 ± 17.1 vs 119.6 ± 12.6 mmHg, $P < 0.05$). After PTX, both systolic (127.6 ± 17.1 vs 124.6 ± 16.6 mmHg, $P < 0.05$) and diastolic (80.3 ± 9.6 vs 78.4 ± 8.6 mmHg, $P < 0.05$) BP decreased.

Conclusions: Our results indicate that patients with PHPT without cardiovascular risk factors have a normal global systolic and diastolic function and cardiac morphology. BP and the systolic velocities were marginally reduced after PTX, but reflected the values of the control group. Our findings warrant further investigation of the clinical and prognostic significance of these possibly disease-related inotropic effects.

European Journal of Endocrinology 163 461–467

Introduction

Primary hyperparathyroidism (PHPT) is a common endocrine disorder; in most cases, it is caused by a solitary parathyroid adenoma (1). The prevalence is highest in postmenopausal women, i.e. 3–4% (2). In recent decades, the clinical profile has shifted towards a less marked symptomatology. Today, the majority of patients with newly diagnosed PHPT show none of the classic symptoms or signs traditionally associated with the disease. The only cure for PHPT is surgical removal of the abnormal parathyroid gland/glands. Although most experts agree that all patients with so-called classic symptoms of PHPT should be offered parathyroidectomy (PTX), there is still a controversy about which patients can be handled conservatively (3).

PHPT has been associated with increased cardiovascular mortality and morbidity. Some of the reported abnormalities are diastolic myocardial dysfunction, left

ventricular hypertrophy, hypertension, autonomic imbalance, metabolic disturbances and endothelial vasodilatory dysfunction with varying normalization after PTX (4–11). However, the extent and clinical significance of cardiovascular risk factors coupled to PHPT are matters for discussion. Conflicting data have been reported on the incidence of cardiovascular disorders in mild PHPT (12–15). It has been argued that the risk of cardiovascular complications is coupled to more severe disease (16). Our knowledge of cardiovascular abnormalities in PHPT is mostly based on data from cohorts that include patients with pre-existing cardiovascular risk factors or diseases that may confound the results. The aim of our study was to evaluate cardiac structure and function using echocardiography and Doppler tissue imaging (DTI) in patients with mild PHPT, without cardiovascular risk factors, before and after PTX and in comparison to healthy controls.

Materials and methods

Study design

Analysis was carried out by the intention-to-treat method in a prospective study design. Patients and controls underwent blood analyses, echocardiography, and DTI at baseline, and the patients were re-examined a mean of 15 ± 4 months after successful PTX.

Subjects

The patient population was consecutively recruited from the referrals for parathyroid surgery due to PHPT at the Karolinska University Hospital in Stockholm, Sweden, between January 2006 and November 2008. During the study period, a total of 410 PHPT patients (319 women) were treated with PTX at the clinic. The following inclusion criteria were used: patients with PHPT who fulfilled the criteria for PTX, no history of cardiovascular diseases or any other disease known to affect the cardiovascular system, no medication affecting the cardiovascular system, no diabetes mellitus or renal diseases, no arterial hypertension (defined as systolic blood pressure (SBP) > 140 mmHg and diastolic blood pressure (DBP) > 90 mmHg), body mass index (BMI) < 28 , and age > 18 and < 70 years. Fifty-three patients met the inclusion criteria. After inclusion, two patients were excluded from the study. One woman regretted her decision to undergo PTX. One man underwent parathyroid exploration with the finding of normal parathyroids; later, mutation analysis verified the diagnosis of familial hypocalciuric hypercalcemia. A majority of the patients had no overt symptoms or signs associated with PHPT; except for a history of kidney stone disease ($n=9$) and bone mineral density below -2.5 at any site ($n=6$). The healthy control group (age- and gender-matched) was randomly selected from the population registry of the city of Stockholm. They were asked to participate in the study by mail and included if they fulfilled the inclusion criteria described above. Two controls were replaced before entering the study, one because of a high P-parathyroid hormone (PTH) level and the other because of hypertension. Finally, 51 patients and 51 controls (16 men and 35 women) were included in the study. Fifty patients were re-examined with echocardiography and DTI after a mean follow-up time of 15 ± 4 months (range 7–28 months); one woman only participated in the blood analyses at follow-up. BMI was calculated by dividing weight (kg) by the square of height (m). Body surface area (BSA) was calculated by the following formula: $BSA = (0.0001) \times (71.84) \times (\text{weight})^{0.425} \times (\text{height})^{0.725}$, where weight was measured in kilograms and height in centimetres.

Each subject gave written consent to participate in the study, which was approved by the ethics committee of the Karolinska Institute in Stockholm, Sweden.

Laboratory methods

Biochemical variables were estimated after an overnight fast by anaerobic sampling before and 15 ± 4 months after PTX. Clinical routine methods were used to estimate the values for total plasma calcium, albumin, creatinine, glucose, phosphate, TSH (Synchro LX® 20 system, Beckman Coulter Inc., Brea, CA, USA), serum-ionized calcium (Ca^{++}) (ABL 800, Radiometer, Copenhagen, Denmark), intact plasma PTH (electrochemiluminescence immunoassay on the Modular E system, Roche Diagnostics GmbH, Mannheim, Germany), and pro-brain natriuretic peptide (NT-pro-BNP).

Blood pressure

Blood pressure (BP) was measured in both arms after at least 30 min of rest, using an appropriately sized cuff and automatic monitor (Digital Automatic Blood Pressure Monitor, Omron Healthcare Kyoto, Japan). The mean values of systolic and diastolic pressure in the two arms were calculated, and heart rate was noted.

Echocardiography

All examinations were performed by one experienced echocardiographer, using an ultrasound scanner Vivid 7 (General Electric, Horten, Norway) equipped with DTI capabilities. The patients were placed in the left lateral recumbent position, and the two-dimensional, M-mode, and Doppler echocardiography was performed in accordance with the guidelines of the American Society of Echocardiography (17). All images were stored digitally on an ultrasound database Echopac. Standard echocardiographic measurements included right ventricular end-diastolic diameter, left ventricular (LV) end-diastolic diameter (LVDd) and end-systolic diameter (LVDs), end-diastolic interventricular septum thickness (IVSd), and left ventricular posterior wall thickness (PWTd). The fractional shortening (FS %), ejection fraction (EF %), and atrioventricular plane (AV-plane) displacement were calculated from M-mode recordings. LV mass was calculated by the following formula: $\text{LVM (grams)} = 0.8 (1.05 ((\text{LVDd} + \text{IVSd} + \text{PWTd})^3 - (\text{LVDd})^3))$ (18). The LV mass was divided by BSA to calculate the LV mass index (LVMI). The cut-off points for LV hypertrophy (LVH) using the LVM/BSA ratio were 150 g/m^2 for males and 120 g/m^2 for females (19). Relative wall thickness (RWT) was calculated according to the following formula: $\text{RTW} = (\text{IVS} + \text{PWT})/\text{LVDd}$. From the calculation of RWT, two geometric patterns of LVH could be established as follows: a concentric pattern, when RWT was ≥ 0.42 , and an eccentric pattern, when $\text{RWT} \leq 0.42$ (17). Transmitral inflow and pulmonary venous flow velocities were acquired with pulsed wave Doppler. The velocities of early transmitral diastolic flow (E) and flow velocity during atrial contraction (A), its ratio (E/A),

deceleration time (DT), and isovolumic relaxation time (IVRT) were measured. The maximal left atrial area was traced at end systole in a four-chamber view.

Doppler tissue imaging

Pulsed Doppler DTI was recorded in the apical four-chamber view at three sites: the tricuspid annulus for the right ventricle (RV) and in the septal and lateral parts of the mitral annulus for the left ventricle (LV). A 3 mm sampling volume was used. Peak systolic (*S'*), early diastolic (*E'*), and late diastolic (*A'*) velocities recorded by DTI were measured. *E'/A'* and *E/E'* for the septal and the lateral part of the mitral annulus were calculated.

Image analyses

All variables describing cardiac dimensions and structure were analyzed off-line by one observer unaware of the patient's status. The remaining Doppler-derived variables were analyzed by another observer. All measurements were averaged from at least three heartbeats. To assess the measurement variability, the two observers re-measured 20 randomly selected echocardiographic and DTI examinations. The coefficient of variation (CV) was calculated for variables for the determination of inter- and intra-observer variabilities. CV was calculated as the mean percent error, defined as the standard error of the absolute difference between the two sets of measurements, divided by the mean of the two measurements.

RWT (cm)	0.36 $\pm$ 0.05	0.37 $\pm$ 0.05	0.37 $\pm$ 0.05	NS	NS
LVMl (g/m ²)					
Males	93.7 $\pm$ 11.7	99.3 $\pm$ 18.4	98.4 $\pm$ 16.0	NS	NS
Females	80.6 $\pm$ 20.1	81.8 $\pm$ 12.3	80.4 $\pm$ 14.8	NS	NS

BP, blood pressure; RVDd, right ventricular end-diastolic dimension; LVDd, left ventricular end-diastolic dimension; LVDs, left ventricular end-systolic dimension; IVS, interventricular septum thickness; PWT, left ventricular posterior wall thickness; RWT, relative wall thickness; LVM, left ventricular mass; LVMl, left ventricular mass index.

The CV for DTI-assessed myocardial velocities was 3–4% for inter-observer and 2–3% for intra-observer analyses. The CV for transmitral flow velocities were 2–4% for inter-observer and 1–2% for intra-observer. The CV for M-mode AV-plane displacement was 2–4% for inter-observer and 2–3% for intra-observer analyses.

Statistical analysis

The sample size was based on differences and s.d. of diastolic function from earlier studies to guarantee a power level of 80% at a confidence level of 95% (20, 21). Statistical analysis was performed with the SPSS for Windows statistical package 17.0 (SPSS Inc., Chicago, IL, USA). Data are expressed as mean $\pm$ s.d. Comparisons between the group of patients at baseline and the control group were performed with the Mann–Whitney *U* test for unpaired data. Wilcoxon signed rank sum test was used for intra-individual analyses. Relationships between variables were assessed with Spearman's ρ correlation test. All tests were done two-tailed, and $P < 0.05$ was considered to be statistically significant.

Results

Clinical and biochemical results

Forty-eight patients had a single parathyroid adenoma removed; three patients had multiglandular disease. Normocalcemia was achieved in 49 of 51 patients after the first PTX; the other two patients became normocalcemic after a second operation when a second parathyroid adenoma and an intrathyroidal adenoma respectively were removed. All patients were normocalcemic at the postoperative follow-up 1 month after PTX (not shown). There were no PTX-related complications. The mean total wet weight of the excised abnormal parathyroid tissue was 619 ± 837 mg. The patients were re-examined a mean of 15 ± 4 (median 14.8) months after successful PTX. Three patients were re-examined < 1 year after surgery (7, 10, and 11 months respectively). At the follow-up, PTH levels were slightly elevated (mean 78 ± 9 ng/l) in combination with normal serum calcium (mean Ca^{++} 1.24 ± 0.04 mM/l) in seven cases. Ca^{++} was elevated in two cases (one woman on vitamin D treatment with 1.45 mM/l Ca^{++} and 37 ng/l PTH in whom Ca^{++} normalized after discontinuation of vitamin D and another woman with 1.36 mM/l Ca^{++} and 62 ng/l PTH). Clinical and biochemical data of patients and controls are given at baseline and after PTX in Table 1. Plasma-intact PTH, calcium, and serum Ca^{++} were significantly higher in patients at baseline compared to healthy controls, while plasma phosphate levels were significantly lower (Table 1). PTH, calcium, and phosphate concentrations normalized after PTX and did not differ from controls at the follow-up visit (Table 1). All subjects fulfilled the BP criteria ($\text{SBP} \leq 140$

and $\text{DBP} \leq 90$ mmHg) before inclusion. At baseline measurements, SBP was > 140 mmHg in 11 patients and 4 controls (range of all subjects is 180–95 mmHg), and DBP was > 90 mmHg in 9 patients (range of all subjects is 110–55 mmHg). SBP was significantly higher in the PHPT group compared to controls and decreased after PTX (Table 2). SBP correlated to the age ($r = 0.45$; $P < 0.001$) as well as to the levels of PTH ($r = 0.26$; $P < 0.01$, Fig. 1a) and Ca^{++} ($r = 0.25$; $P < 0.05$, Fig. 1b). DBP decreased after PTX (Table 2).

BMI increased after PTX only in female PHPT (23.5 ± 2.7 vs 24.3 ± 3.3 kg/m², $P < 0.01$), but not in male PHPT (25.3 ± 3.0 vs 25.6 ± 3.7 kg/m², $P = \text{NS}$). In female PHPT, the weight of the excised abnormal parathyroid tissue correlated to the PTH but not to Ca^{++} ($r = 0.52$; $P < 0.001$). Among men, there was a strong correlation between adenoma weight and Ca^{++} ($r = 0.89$; $P < 0.01$) but not to PTH. The phosphate level

Figure 1 Systolic blood pressure for the whole group of PHPT patients and the healthy control subjects was correlated to (a) the PTH level ($r = 0.26$; $P < 0.01$) and to (b) the ionized calcium level ($r = 0.25$; $P < 0.05$).

^c $n = 49-50$.

(0.87 $\pm$ 0.16 vs 0.76 $\pm$ 0.13 mM/L, $P < 0.05$) was higher in the female group of PHPT compared to male PHPT patients.

Echocardiographic results

There were no differences between the groups in the variables describing cardiac dimensions and structure (Table 2). The systolic and diastolic LV function evaluated by Doppler echocardiography was within normal limits, and there were no differences between the groups at baseline (Table 3). The regional peak systolic myocardial velocities (*S'*) measured with DTI in the base of the RVs and LVs decreased after PTX (Table 3). For variables with a significant change after PTX, we also tested post-PTX results for possible differences compared to the control group. Compared to our age- and gender-matched healthy controls, the PHPT group had numerically lower peak systolic velocities after PTX, but the difference reached a statistical significance only in the lateral part of the mitral annulus (Table 3). For comparison, previously published normal values for DTI myocardial velocities for RVs and LVs are shown in Table 3 (22, 23). The values are in the same range as in our healthy control group.

The peak systolic velocity of the septal part of the mitral annulus correlated significantly and positively to the Ca^{++} level ($r = 0.4$; $P < 0.05$) in the PHPT group at baseline. IVRT was increased in the male PHPT group

compared to female PHPT and the healthy controls (97 $\pm$ 20 vs 82 $\pm$ 15, 84 $\pm$ 13, $P < 0.05$). The *E/A* ratio was inversely correlated to the PTH level ($r = -0.33$; $P < 0.01$), SBP ($r = -0.40$; $P < 0.01$), and DBP ($r = -0.46$; $P < 0.01$).

Discussion

The present study was conducted to evaluate cardiac function and the effect of PTX in patients with mild PHPT. The main strength of our study is the strict design, excluding PHPT patients with known cardiovascular risk factors. The PHPT patients included in this study made up about one-tenth of all the PHPT patients treated with PTX at our clinic during the time period. Men made up 31% of our study cohort compared with 22% of our unselected control cohort. We observed no differences in global systolic or diastolic function, or cardiac morphology, in our PHPT patients compared to the age-matched healthy controls. The regional peak systolic myocardial velocities in the RVs and LVs in our study correspond to normal values described previously (22, 23). However, the PHPT patients did show a significant decrease in BP and regional peak systolic myocardial velocities after PTX. In one site, the regional peak systolic myocardial velocities were significantly lower in patients after PTX compared to healthy controls. Our results indicate that patients with mild PHPT without any other known cardiovascular risk factors

have a higher systolic myocardial performance at baseline, which seems to be associated with the level of PTH and Ca^{++} . The clinical significance of these findings is not clear. Hypothetically, a disease-related inotropic effect may result in increased vascular resistance and in an increased cardiac workload. Our hypothesis is supported by the results of a study that compared patients with mild PHPT randomized to PTX either directly or after 1 year of observation (24). In that study, some of the systolic and diastolic function parameters decreased after PTX when the PTH and calcium levels had normalized. The functional changes observed were transient, and the values in question returned to preoperative levels within 1 year. This reaction pattern was interpreted as a withdrawal inotropic effect of PTH. The authors also found higher LVMI in the group of patients followed without surgery, and the extent of the LVMI increase was associated with PTH. These findings support our hypothesis of a supra-systolic performance that may promote cardiac hypertrophy and morbidity. Cook *et al.* (25) concluded, from a longitudinal cohort study, that a small reduction of 2 mmHg in DBP in the population, in addition to medical treatment, could have a major public health impact on the risk of coronary heart disease and of stroke events. Only a few studies have reported a decrease in BP after PTX (5, 12). Recently, Bollerslev *et al.* (12) have reported, from a randomized study, declines in BP in both surgical and observation groups of PHPT patients with mild hypercalcemia.

To our knowledge, DTI has only been used once before to evaluate cardiac function in PHPT patients. Baycan *et al.* (26) reported small differences in some variables of diastolic function in PHPT patients without hypertension, diabetes mellitus, and coronary artery disease. Similar to Baycan *et al.*, we observed prolonged IVRT in our study, but only in the male PHPT group in comparison to female PHPT and healthy male controls. We also found an inverse correlation between E/A ratio and PTH. The clinical importance of these subtle findings is unclear, but they may represent signs of early diastolic dysfunction.

Available data on the extent and reversibility of cardiovascular morbidity in PHPT and the coupling to biochemical disturbances are conflicting (15). Based on a large population study, Kamycheva *et al.* (27) reported serum PTH to be an independent predictor of coronary heart disease in both sexes. Bergenfelz *et al.* (28) concluded that a normal PTH level in PHPT is associated with a milder form of disease and smaller adenomas, while the calcium level did not reflect disease severity. Recently, Walker *et al.* (29) have reported subclinical carotid vascular manifestations in mild PHPT associated with the extent of PTH elevation. The duration of the disease is probably an important prognostic factor, suggesting benefits of early surgical cure of mild PHPT before irreversible cardiovascular manifestations may occur (5, 29).

To conclude, our results indicate that patients with PHPT without cardiovascular risk factors have a normal cardiac morphology and function. The BP and the systolic velocities were marginally reduced after PTX but reflected the values of the control group. Our findings warrant further investigation of the clinical and prognostic significance of these possibly disease-related inotropic effects.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.
