Abstract

Objective: Patients with cortisol deficiency poorly tolerate any systemic inflammatory response syndrome (SIRS), and may die if not treated with sufficient exogenous glucocorticoids. Controversy surrounds what constitutes a ‘normal’ adrenal response in critical illness. This study uses conventional tests for adrenal insufficiency to investigate cortisol status in patients undergoing elective coronary artery bypass surgery, a condition frequently associated with SIRS.

Design: A prospective, observational study.

Methods: Thirty patients with impaired left ventricular function (ejection fraction < 30%) underwent basal ACTH measurement, and a short cosyntropin test (250 μg, i.v.) 1 week preoperatively, and at +4 h following induction of general anaesthesia. Preoperatively, a 30 min cortisol level post cosyntropin > 550 nmol/l was taken as a normal response.

Results: Prior to surgery, all patients had a normal response to cosyntropin. Postoperatively, eight patients (26.7%) did not achieve stimulated cortisol levels > 550 nmol/l and the mean peak cortisol postoperatively was lower (1048 vs 730 nmol/l; P < 0.001). There was a significant rise in ACTH after surgery (21 vs 184 ng/l; P < 0.001) and reduction in Δ-cortisol post cosyntropin (579 vs 229 nmol/l; P < 0.001). There was no change in basal cortisol pre- and post-operatively (447 vs 501; P = 0.4). All patients underwent routine, uneventful postoperative recovery.

Conclusion: Up to one quarter of patients with a normal cortisol status preoperatively demonstrated a raised ACTH and deficient cortisol response postoperatively. Despite these responses, all patients had uneventful outcomes. These data reinforce the need for caution when interpreting results of endocrine testing following major surgery or in the intensive care environment, and that prognostic value of these results may be of limited use.

European Journal of Endocrinology 164 413–419

Introduction

Cortisol is a critical player in the endocrine response to stress and is essential for survival in critical illness (1). Activation of the hypothalamic–pituitary–adrenal (HPA) axis represents one of several important responses to physiological stresses, such as surgery and critical illness. Despite a large volume of published data on this topic, controversy remains as to the definition of a ‘normal’ adrenal response, and what is meant by the concept of relative adrenal insufficiency or critical illness-related corticosteroid insufficiency (CIRCI) (2).

In the unstressed subject, cortisol has a distinct circadian rhythm: high on waking and low on going to sleep (3). In contrast, surgery stimulates both the endocrine and immune systems to mount a systemic reaction to the associated injury as part of the healing process and cortisol levels may increase to 830–1400 nmol/l, with phase shifting of the physiological rhythm depending on the degree of surgical stress (4, 5). This principally occurs through cytokine regulation of the HPA axis primarily by direct or indirect stimulation of hypothalamic CRH, especially by IL1, IL6, and tumour necrosis factor α (TNFα), and also by directly affecting the pituitary and adrenal glands (6). To balance the inflammatory response, IL10 acts as an immunosuppressant neutralising pro-inflammatory effects (7). In a subpopulation of patients exposed to cardiopulmonary bypass (CPB), this systemic reaction can propagate a huge pro-inflammatory response, similar to that seen in sepsis. The systemic inflammatory response syndrome (SIRS) describes the clinical manifestation of this response (8) and progression to an advanced stage of SIRS is associated with prolonged cardiovascular support and a high mortality.
Studies generally show that during surgery the HPA is activated especially after extubation, whereby plasma ACTH levels are increased and are associated with elevated serum cortisol concentrations. Thereafter, plasma levels of ACTH decline rapidly to normal levels, whereas serum cortisol concentrations decrease slowly, reaching high normal values ~48–72 h after the procedure (9). This has been confirmed in coronary artery bypass graft operations, associated with SIRS consequent to sternotomy and CPB, where basal and stimulated cortisol levels have been correlated with severity of stress, peaking shortly after extubation and being similar to levels during other major surgical procedures and critical illness (10).

It has been stated that adrenal insufficiency is rare in the setting of critical illness (11), but the methods commonly used to make the diagnosis of adrenal insufficiency are not necessarily applicable in the critically ill patient, and the incidence may therefore have been underestimated. In contrast, other authors have reported significantly higher rates of insufficient adrenal response in critical illness (12) especially in those with a prolonged stay in ICU, and in those over 55 years of age (13–15). In view of such conflicting published data, we performed a prospective study to investigate the immediate impact of major surgery on the tests used to diagnose adrenal insufficiency.

Subjects and methods

Study population

A prospective, observational study was performed at Sheffield Teaching Hospitals Cardio-Thoracic Surgical Unit and Cardiac Intensive Care Unit to analyse tests for adrenal insufficiency pre- and post-operatively. The study was also set up to examine the impact of low-dose hydrocortisone therapy, and patients were randomised to treatment with a low-dose hydrocortisone infusion or placebo after all tests, assessing each participant’s adrenal status, were complete. However, measurement of cortisol levels during the infusion showed no difference between the groups and this data has not been included in the analysis of the 30 patients reported in this article. Thirty consecutive patients, >17 years of age with impaired left ventricular function (ejection fraction >23% <50%), were recruited. Patients with severe ventricular electrical irritability, congenital or valvular heart disease, cardiac ejection fraction <23%, systemic corticosteroids within the previous 3 months, severe renal impairment (creatinine >200 µmol/dl), asthma, insulin-treated diabetes, those needing emergency cardiac surgery and those with an abnormal cortisol response (peak cortisol <550 nmol/l) after a 250 µg cosyntropin test were excluded. These criteria were used in an effort to ensure that as homogenous population as possible was recruited. The study was approved by the North Sheffield Research ethics committee and all patients gave written informed consent prior to participation in the trial.

Materials and methods

One week prior to surgery, the patients had basal ACTH and a short cosyntropin test for adrenal function. Immediately prior to surgery, a pulmonary artery flotation catheter (Baxter Healthcare Corp., Irvine, CA, USA) was placed for cardiovascular monitoring. Use of etomidate, which causes reversible inhibition of the adrenal 11β-hydroxylase, was avoided for anaesthetic induction. Following induction of anaesthesia and sternotomy, patients were placed on CPB during coronary artery grafting and on completion were weaned off CPB. Inotrope support was commenced where necessary as decided by the anaesthetist and surgeon. Patients were then transferred to the CICU, received routine recovery care and had a postoperative cosyntropin test around 4 h from the time of induction. All operations were complete by this time. The parameters related to surgery were measured: CPB time, aortic cross-clamping time and total theatre time (Table 1).

The following tests were analysed pre- and post-operatively: basal cortisol, stimulated 30 min cortisol post cosyntropin (peak cortisol), difference between stimulated and basal cortisol (Δ-cortisol) post cosyntropin (peak−basal), percentage change in cortisol (100% × peak−basal cortisol/basal cortisol), ACTH, cortisol/ACTH. A stimulated cortisol level <550 nmol/l and a Δ-cortisol <250 nmol/l post cosyntropin were taken as abnormal responses, since a normal response is widely regarded as a 30 min cortisol value >550 nmol/l (16–18) and a Δ-cortisol >250 nmol/l. The latter has been used previously as a criterion for a normal adrenal response in studies investigating the HPA axis during septic shock (19–21). High ACTH levels in the presence of relatively low cortisol values, that is a low cortisol/ACTH, may be indicative of primary adrenal insufficiency, while low to normal ACTH levels in the presence of low cortisol values are principally indicative of secondary adrenal insufficiency (22, 23).

The following were deemed indicative of an adverse event: tachycardia (sustained (>5 min) pulse rate >130% baseline), hypertension (sustained (>5 min)

CPB, cardiopulmonary bypass; AXC, aortic cross-clamping.
mean arterial pressure > 130% baseline), hypotension (sustained (> 5 min) mean arterial pressure < 70% baseline), presence of myocardial ischaemia (new, sustained (> 5 min) ST changes > 1.0 mm ST depression/elevation), new arrhythmias and failure to wean from bypass.

**Assays**

Total serum cortisol was measured in a Siemens Adiva Centaur Cortisol assay: analytical range 5.5–2069 nmol/l; inter-assay coefficient of variation (CV), 6.2% at 134 nmol/l, 5.5% at 491 nmol/l and 6.0% at 837 nmol/l. Normal 0900 h cortisol reference range was 198–720 nmol/l. Plasma ACTH was measured in a Siemens Immulite 2000 chemiluminescent assay: analytical range 5–1250 ng/l; inter-assay CV values, 6.4% at 32.1 ng/l, 6.5% at 478 ng/l. Normal 0900 h ACTH reference range was < 46 ng/l.

**Statistical analysis**

Database management and all statistical analyses were performed using SPSS Version 15.0 (IBM Corporation, Somers, NY, USA) and Microsoft Excel Version 2007. Rates and percentages were calculated for categorical data, and means and 95% confidence intervals (CIs) for continuous data. For continuous variables, differences within the same group were analysed by the paired sample t-test. Correlation analyses were determined by calculating Pearson’s r coefficient. A significant result was taken as P < 0.05.

**Results**

Thirty patients were recruited and all patients completed the study. Demographic data are shown in Table 1.

**Basal and 250 µg cosyntropin-stimulated cortisol levels**

Preoperatively, all patients achieved a 30 min cortisol level > 550 nmol/l after the cosyntropin test, thereby excluding adrenal insufficiency. Mean (95% CI) preoperative basal cortisol and cosyntropin-stimulated cortisol levels were 447.0 (385.4–508.6) nmol/l and 1048 (945–1151) nmol/l respectively. There was no significant difference in the basal postoperative mean cortisol level 501 (393–609) nmol/l compared with preoperative levels (P = 0.4), but there was a significant difference in the postoperative cosyntropin-stimulated mean cortisol 730.2 (632.2–828.2) nmol/l (P < 0.001) compared to the preoperative value. Eight patients (26.7%) had stimulated cortisol levels < 550 nmol/l postoperatively (Fig. 1).

**Figure 1** Changes between mean (± 95% CI) pre- and post-operative measurements of (i) basal cortisol (447 (385–509) vs 501 (393–609) nmol/l; P = 0.4), (ii) stimulated 30 min cortisol post cosyntropin (peak cortisol) (1048 (945–1151) vs 730.1 (632–828) nmol/l; P < 0.001), (iii) Δ-cortisol post cosyntropin (peak–basal) 579 (504–654) vs 229 (170–288) nmol/l; P < 0.001), (iv) percentage change in cortisol (100% × peak–basal cortisol/basal cortisol) 161 (112–210) vs 77 (45–107); P = 0.002 estimated by paired sample t-test. Bold lines (mean); light lines (individual values).

No correlation was found between basal or stimulated pre- and post-operative cortisol values but there was a significant strong correlation between postoperative basal and stimulated cortisol levels (r = 0.841; P < 0.001) (Fig. 2).

All patients had a Δ-cortisol, that is the difference between stimulated cortisol (peak) and basal cortisol, > 250 nmol/l preoperatively while 17/30 (57%) had a Δ-cortisol < 250 nmol/l postoperatively. The mean (95% CI) Δ-cortisol preoperatively was 578.6 (503.7–653.5) nmol/l, with a mean percentage change of 161% (112–210), while that postoperatively was 229.1 (170.4–287.8) nmol/l with a mean percentage change of 76.5% (45.5–107.5). A significant difference was shown when comparing pre- and post-operative mean Δ-cortisol (P < 0.001), and

**Figure 2** Pearson’s correlation between postoperative (i) basal cortisol and stimulated (peak) cortisol post cosyntropin (r = 0.84; P < 0.001) and (ii) Δ-cortisol and stimulated (peak) cortisol post cosyntropin (r = 0.4; P = 0.04). These correlations potentially highlighting lack of adrenal sensitivity to endogenous ACTH and cosyntropin in a number of individuals immediately post CABG.
pre- and postoperative percentage change in cortisol ($P = 0.002$). Percentage change in cortisol $= 100\% \times$ peak–basal cortisol/basal cortisol (Fig. 1).

There was no correlation between pre- and postoperative $\Delta$-cortisol ($r = 0.09; P = 0.6$) or percentage change in cortisol levels ($r = 0.2; P = 0.4$). Analysis of postoperative tests showed a significantly weak correlation between $\Delta$-cortisol and stimulated (peak) cortisol levels ($r = 0.4; P = 0.04$) (Fig. 2).

**ACTH and cortisol/ACTH ratios**

Mean (95% CI) basal ACTH levels preoperatively were $21.1$ ng/l (16.4–25.8), all were within the normal reference range. Compared with preoperative levels, there was a significant increase in ACTH levels to $183.8$ (71.9–295.7) ng/l ($P = 0.007$) postoperatively. The mean basal cortisol/ACTH ratio preoperatively was $24.0$ (21.24–26.76) and this was significantly different ($P < 0.001$) to the postoperative mean level of 8.9 (6.08–11.7) (Fig. 3).

Both preoperative ACTH and postoperative ACTH correlated significantly with preoperative ($r = 0.7; P < 0.001$) and postoperative ($r = 0.433; P = 0.017$) basal cortisol levels respectively but the correlation was weaker postoperatively (Fig. 4).

**Patient outcomes**

Only one patient had an episode of sustained hypotension. His postoperative basal cortisol was $245$ nmol/l, stimulated cortisol $364$ nmol/l, $\Delta$-cortisol $119$ nmol/l and cortisol/ACTH ratio 3.61. He remained intubated for 17 h and was on inotropes for 21 h. He was not given corticosteroids and was discharged from CICU after <24 h. This patient had a temperature >38.3 $^\circ$C and a raised WCC of $12.1 \times 10^3$; 11/22 patients with a response to cosyntropin >550 nmol/l and 5/8 patients with a response <550 nmol/l required inotropes. One patient had sustained tachycardia, one other patient had sustained hypertension and two patients had ischaemic episodes. One patient had sustained tachycardia, hypertension and an ischaemic episode.

**Discussion**

We have shown that up to a quarter of patients with a normal HPA axis preoperatively have a reduced cortisol response to cosyntropin immediately following coronary arterial bypass grafting surgery. The advantage of this study is the demonstration of a normal HPA axis preoperatively. During stressful events, the HPA axis is activated with a resultant increase in ACTH and cortisol levels (24). Cortisol at these levels then exerts its suppressive or anti-inflammatory effects, which are crucial for re-establishing homeostasis. In patients undergoing coronary artery bypass surgery (CABG), cortisol levels around 1200 nmol/l have been shown to suppress plasma IL6 while significantly increasing plasma IL10 potentiating the anti-inflammatory response (25). Our results differ from previous publications as although ACTH was elevated postoperatively the basal cortisol was not increased and thus the ratio of cortisol to ACTH was reduced. These results may suggest an element of insensitivity to ACTH. Our patients were studied immediately after surgery in contrast to previous studies, which were undertaken at the time of extubation (10).

In studies investigating the adrenal response to critical illness, results have been conflicting and no defined criteria exist. Most publications have adopted the serum cortisol response to the standard cosyntropin test (250 $\mu$g, i.v.) to characterise patients as ‘responders’ (those who had an increment of >250 nmol/l in serum cortisol) and ‘non-responders’ (those who had an increment of <250 nmol/l in their serum cortisol levels), regardless of their baseline values (19, 20). Other studies evaluated the prognostic value of measuring baseline and cosyntropin-stimulated serum cortisol (20, 26, 27). Proposed lower thresholds for stress-elevated basal cortisol concentrations vary widely in the literature and it has been proposed that cortisol levels <414 nmol/l are in keeping with adrenal insufficiency, while stimulated or non-stimulated levels >827–940 nmol/l are unlikely to indicate any
deficiency (9, 12). In the Corticosteroid Therapy for Septic Shock (CORTICUS) study, investigating the use of i.v. hydrocortisone in patients with septic shock, it was shown that hydrocortisone did not significantly improve survival in patients who did not respond to cosyntropin (Δ-cortisol after cosyntropin < 250 nmol/l) (28). Hence, the cosyntropin test was deemed not to be useful in determining which patients should receive hydrocortisone therapy.

This study showed that the adrenal status of patients undergoing major stress during a CABG showed significant changes, with many not achieving the criteria for adrenal sufficiency. All tests were normal prior to surgery but 4 h postoperatively there was a significant difference in ACTH, cortisol/ACTH ratios and response to cosyntropin. Around 25% of patients failed to achieve a stimulated cortisol > 550 nmol/l post cosyntropin and this was not predictable from preoperative tests. An equal number of individuals from those either failing or passing the cosyntropin test required inotropes. Interestingly, there was no significant difference in basal cortisol levels pre- and postoperatively. Previously, it was shown that during CABG maximal cortisol levels were achieved post extubation with maximal stress (10). Adrenal status tests in our patients were performed 4 h after induction while most patients were still intubated (mean time for extubation 7.2 h) and therefore potentially a further rise in cortisol levels may have been expected if the tests were done later. Irrespective, at this point of the surgical procedure one would have expected mean cortisol levels higher than 501 nmol/l, as measured in our patients. Further, 57% of patients did not achieve Δ-cortisol > 250 nmol/l post cosyntropin. The clinical outcome for all these patients was not significantly different from those who did achieve a change in cortisol > 250 nmol/l and postoperative recovery was uneventful.

A reason for an apparent lower baseline cortisol or stimulated cortisol could be related to these being measured as total cortisol levels. Total cortisol, during major surgery or illness with associated hypoalbuminaemia and low cortisol-binding globulin (CBG), will be low, although free cortisol levels, the fraction of cortisol exerting physiological function, may be normal or high (29). This possibly explains why our patients had a good final outcome, as in general glucocorticoid secretion would have been increased although this was not discernible in this case. Measuring albumin and CBG levels together with estimations of free cortisol in patients undergoing CABG would be useful to help clarify this hypothesis (30). Dilution of proteins, such as CBG and albumin, due to the large amount of fluids given to patients during resuscitation results in a lower level of measured total cortisol. This has previously been reported in patients undergoing CABG (31) in which there was a highly significant correlation between the degree of haemodilution and the percentage rise in the free cortisol fraction.

Potentially, a low baseline cortisol and a low stimulated cortisol could also represent an element of relative adrenal insufficiency or CIRCI. This must have been short lived as all patients recovered from surgery. CIRCI is defined as inadequate corticosteroid activity for the severity of the illness of a patient secondary to either glucocorticoid resistance or HPA axis failure (2). In glucocorticoid resistance, in the face of excessive cytokine production during critical illness, there is a decreased number and binding affinity of glucocorticoid receptors, with post receptor alterations resulting in high cortisol levels (32). Alternatively, various factors have been suggested to influence the HPA axis and confound its evaluation. Both primary and secondary types of adrenal insufficiency have been reported to occur during critical illness (33, 34). The results from this study show an impaired adrenal response to cosyntropin with a low cortisol/ACTH ratio postoperatively in keeping with primary adrenal failure. A number of mechanisms may be responsible. TNFα reduces adrenal cortisol synthesis by reducing the sensitivity of adrenal receptors to ACTH resulting in a blunted response to cosyntropin and high ACTH levels with relatively low cortisol levels in the setting of acute illness (35). In addition, corticostatins or defensins produced by cells, such as macrophages and neutrophils, and which may proliferate in a systemic inflammatory response, inhibit the steroidogenic activity of ACTH. They have been shown to increase 20-fold in plasma and 10-fold in adrenal tissue during bacterial infection in rabbits (36). Corticostatins compete with ACTH on their binding sites and exert an inhibitory effect on the adrenal cells resulting in decreased cortisol production (37, 38). Another possible mechanism for primary adrenal failure is the release of a number of factors by lipopolysaccharide-stimulated macrophages, similar as to what happens in endotoxic shock, that suppress the steroidogenic response of adrenocortical cells to ACTH, the amount of factors released regulated by lymphokines (39). Furthermore, transforming growth factor-β, another cytokine derived from monocytes, is also known to inhibit both basal and ACTH-stimulated steroidogenesis (40). A strong correlation identified between postoperative basal and peak cortisol levels and a weaker correlation between ACTH and cortisol postoperatively compared to preoperative values could support this hypothesis. A number of drugs used during surgical procedures are known to affect the HPA axis and direct cortisol production in the adrenal gland. Etomidate, an anaesthetic agent that can reversibly inhibit 11-hydroxylase enzyme and result in decreased cortisol secretion from the adrenal gland (41), was not used in any of the procedures and so does not account for these findings.

Our data confirm that there are limitations in the tests used to assess for adrenal insufficiency in the critically ill patient. Studies have been controversial giving conflicting and unclear results. Baseline serum
cortisol levels and stimulated cortisol, preferably measuring the free cortisol levels, are most probably the most practical tests although further studies to assess the impact of these tests on outcome and their importance in predicting the benefits of glucocorticoids in these scenarios are necessary.
