Abstract

We describe a protocol for etomidate infusion for the emergency management of hypercortisolemia. Etomidate is commenced at 2.5 mg/h and titrated subsequently according to cortisol levels. It is well tolerated without any sedative effects and can be administered safely via peripheral access for use in the general ward setting.

European Journal of Endocrinology 167 727–728

We read with interest the recent paper by Preda et al. (1) in which i.v. etomidate infusion for the management of Cushing’s syndrome was reviewed. The authors advocate its use in an intensive care unit (ICU) to ensure that adrenal insufficiency does not occur. While we agree that etomidate is a vital tool in the management of patients in hypercortisolemic crises, its use need not be confined to the ICU.

The pharmacokinetic properties of etomidate are well documented by Van Hamme et al. (2), and there is a clear dissociation between the higher anaesthetic dose and lower doses, which inhibit adrenal function (3). In clinical studies, this has been demonstrated by Schulte et al. (4), where varying doses of etomidate infusion at 0.03, 0.1 and 0.3 mg/kg per h showed prominent sedation only at the highest dose. Alloio et al. (5) corroborated this in subjects with Cushing’s syndrome, where low-dose etomidate infusion at 2.5 mg/h decreased mean cortisols to 53% in 7 h without any sedative complications.

Against this background, appropriate selection of etomidate dose will minimise any risk of unwanted sedation. We have recently established a protocol for the treatment of Cushing’s syndrome in the general ward. Its creation was driven by necessity, as the availability of critical care beds is often limited (6), with priority naturally given to patients who require ventilatory or inotropic support. This protocol was derived following close liaison between clinical endocrinologists, ICU physicians, pharmacists and nursing staff.

In our institution, etomidate is available in a lipid emulsion, as Etomidate-Lipuro. It is given undiluted via a syringe driver, and the preparation is changed every 24 h. The choice of this preparation circumvents the side effects of hemolysis (7), lactic acidosis and nephrotoxicity (8) associated with propylene glycol. It is also better tolerated with minimal thrombophlebitis and pain (9, 10) and hence can be administered via a peripheral line, thereby avoiding the potential hazards of central venous cannulation. We use a starting dose of 2.5 mg/h irrespective of body weight, which is titrated according to cortisol levels, up to a maximum of 4 mg/h.

Cortisol levels are taken at baseline, 4 h after commencing etomidate, or after each dose titration. Measurement is continued 4 hourly until stable, whereupon the frequency of monitoring may be adjusted. Half hourly observations (blood pressure, heart rate, oxygen saturation and neuro-observations) are taken in the first 2 h, then hourly for the next 4 h, and 4 hourly thereafter. The hypnotic effect of etomidate is enhanced by neuroleptics, opioids, sedatives and alcohol, and concurrent use of these agents should be avoided.

Since implementing the protocol, four patients with severe hypercortisolism from Cushing’s disease have received etomidate in the general ward. None required doses above 3 mg/h to maintain eucortisolemia. When cortisol levels fall < 200 nmol/l, ‘add back’ therapy of hydrocortisone was given as a form of ‘block and replace’ regimen. Our patients received etomidate infusion for a mean of 8.2 (range 2.8–12) days, which was well tolerated, with no neurological or gastrointestinal side effects.

We endorse the views expressed by Preda et al. regarding the clinical use of etomidate in the emergency treatment of Cushing’s syndrome and hope that our report on its use outside the ICU will prove useful to endocrine colleagues faced with the same clinical scenario.
