Abstract

Objective: Excess GH causes insulin resistance and impaired glucose metabolism. The objective of this study was to clarify the prevalence of ketoacidosis as the initial presenting symptom of acromegaly.

Design and methods: Data were collected from 860 patients with acromegaly who underwent pituitary surgery at Toranomon Hospital over the last 32 years, between 1980 and 2011.

Results: Nine cases had ketoacidosis before being diagnosed with acromegaly, including seven males and two females with a mean ± s.d. age of 38.8 ± 14.2 years. Serum GH and IGF1 levels were 155 ± 203 ng/ml and 9.86 ± 0.68 SDS before pituitary surgery and 3.6 ± 1.7 ng/ml and 3.72 ± 3.40 SDS after surgery respectively. The maximum tumor diameter was 28.2 ± 11.6 mm (ranging from 15 to 47 mm, n=8). None of the patients were diagnosed with diabetes mellitus (DM) nor were they positive for antibodies related to type 1 DM. A possible precipitating factor for ketoacidosis in six cases was excessive ingestion of sugar-containing soft drinks. All the cases had invasive pituitary adenomas. After pituitary surgery, plasma glucose levels were under control without requiring insulin in all cases. Furthermore, six patients did not need oral hypoglycemic agents.

Conclusions: Approximately 1% of patients with acromegaly presented with diabetic ketoacidosis as their first clinical condition.

Introduction

Acromegaly is characterized by autonomous secretion of GH, which is usually due to a pituitary somatotropic adenoma. GH stimulates synthesis and secretion of IGF1, especially in the liver (1). Diagnosis of acromegaly is usually delayed for years and leads to increased morbidity and mortality. Excess GH impairs metabolic regulation. Indeed, it is associated with hepatic and peripheral insulin resistance (2). Thus, patients with acromegaly are predisposed to developing diabetes mellitus (DM) in addition to skeletal complications and cardiovascular and respiratory diseases (3). Risk factors for impaired glucose metabolism include high serum levels of GH, older age, longer duration of the disease, family history of DM, and concomitant hypertension (4, 5, 6). The prevalence of diabetes among patients with acromegaly has been reported to range from 19 to 56% (3).

Ketoacidosis is common among patients with type 1 DM. However, it is unusual for ketoacidosis to occur in patients with acromegaly in the absence of type 1 DM. Indeed, there are 18 cases of ketoacidosis complicated with acromegaly in the literature (7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23). Only eight cases with ketoacidosis as the first clinical condition of acromegaly have been anecdotally reported (13, 14, 15, 16, 17, 19, 20, 21). The epidemiology and mechanism of ketoacidosis in acromegaly have not been elucidated. To address these issues, we reviewed 860 cases of acromegaly that were seen at Toranomon Hospital over the last 32 years. Here, we present nine cases that had ketoacidosis as a clinical condition before being diagnosed with acromegaly.

Subjects and methods

Subjects

We reviewed clinical data from 860 acromegaly patients who underwent pituitary surgeries at a single institute, Toranomon Hospital (Tokyo, Japan), consecutively from 1980 to 2011. Charts were reviewed according to the diagnosis and institutional registry data available at the time of pituitary surgery.
We found nine cases whose first clinical condition was ketoacidosis before being diagnosed with acromegaly and evaluated their clinical characteristics. All data had been obtained from routine medical procedures and were collected retrospectively. This study was approved by the institutional review board at Toranomon Hospital.

The diagnosis of acromegaly was based on clinical findings, elevated serum levels of GH and IGF1 after adjusting for age and sex, and the presence of pituitary adenoma based on imaging studies. Although a 75 g oral glucose tolerance test (OGTT) is the standard diagnostic procedure for acromegaly, this test was not performed before surgery in any of the present cases because sufficient hyperglycemia was present in the absence of glucose challenge. A transsphenoidal pituitary adenomectomy was performed on each patient by expert neurosurgeons. The presence of a GH-secreting pituitary adenoma was confirmed by immunohistochemistry in each case. Patients underwent the 75 g OGTT within 1 month of surgery.

**Laboratory tests and their analyses**

Immunoreactive insulin (IRI) was measured by a chemiluminescent enzyme immunoassay (LUMIPULSE Presto insulin, Fujirebio, Inc., Tokyo, Japan). Plasma glucose was measured by the hexokinase method (Liquitech Glucose HK Test, Roche Diagnostics Japan). Serum and urinary C-peptide concentrations were measured with commercially available kits as follows. We used the C-peptide kit ‘Daichi’ (FUJIFILM RI Pharma Co. Ltd., Tokyo, Japan) until January 2003. The Chemilumi C-peptide kit (Siemens Healthcare Diagnostics K. K., Tokyo, Japan) was used until February 2007. The LUMIPULSE Presto C-peptide kit (Fujirebio, Inc.) was used thereafter. The sensitivity of each kit was at least 0.1 ng/ml. The CV values of the intra- and interassays of each kit were <10 and 20% respectively. Serum GH was measured with commercially available kits as follows. The GH RIA kit (Abbot Japan Co. Ltd.) was used until August 1989. The HGH kit ‘EIKEN’ (EIKEN CHEMICAL Co. Ltd., Tokyo, Japan) was used until May 2001. The ST AIA-PACK HGH kit (Tosoh Co., Tokyo, Japan) was used thereafter. Coefficients of correlation for C-peptide and GH were 0.990–0.994 and 0.740–0.910 respectively. IGF1 was measured with an IRMA (IGF1 IRMA Daiichi, TFB Co., Tokyo, Japan).

After surgery, all patients underwent a 75 g OGTT after an overnight fast. Blood samples were collected at baseline and 30, 60, 90, and 120 min after glucose ingestion. IRI, glucose, and GH were measured in blood samples. We used homeostatic model assessment (HOMA) computer software to estimate basal pancreatic β-cell function (HOMA-%B) and insulin resistance (HOMA-IR) from fasting blood glucose and serum IRI levels (24, 25). Insulinogenic index is an OGTT-based
estimate of early-phase insulin secretion, which is calculated as $(IRI_{30\ min} - IRI_{0\ min} (\mu U/ml))/(glucose_{30\ min} - glucose_{0\ min} (mg/dl))$ (26).

**Statistical analysis**

Results are expressed as the mean ± s.d. Student’s t-tests or paired t-tests were applied to determine whether the differences between two groups were statistically significant ($P < 0.05$). Statistical analyses were done with SPSS version 16.0.2.

**Results**

Ketoacidosis was the first clinical condition in ~1.0% of 860 consecutive cases of acromegaly. Table 1 shows the baseline characteristics of patients with ketoacidosis. Nine cases (seven males and two females) were diagnosed with ketoacidosis because they had low arterial blood pH values of 7.27 ± 0.08 and urinary ketones before being diagnosed with acromegaly. All patients with ketoacidosis had hyperglycemia (41.4 ± 21.0 mmol/l) and high HbA1c (12.1 ± 1.8%), suggesting the presence of diabetic ketoacidosis. However, none of the patients had histories of DM nor were they positive for antibodies related to type 1 DM. Overconsumption of alcohol was not reported for any of the subjects. The average age was 38.8 ± 14.2 years. This age was significantly younger than 48.2 ± 13.4 years, which was the average age for the other acromegaly patients ($P < 0.05$). Six patients had recent histories of excessive ingestion of sugar-containing soft drinks in quantities exceeding 2 l/day (Table 1). Medical care was provided for ketoacidosis and hyperglycemia, and all patients were suspected of having acromegaly because of their appearance.

Parameters of intrinsic insulin secretion were evaluated after recovery from ketoacidosis but before pituitary surgery. The insulin secretion capacities were not depleted. The average urine C-peptide was 97 ± 46 mg/day (ranging from 53 to 195 mg/day, $n = 7$). The increase in serum C-peptide 10 min after an i.v. injection of 1 mg glucagon was 3.0 ± 0.6 ng/ml (ranging from 2.3 to 3.3 ng/ml, $n = 3$). At least one of the two parameters was examined in all nine cases. Table 2 shows clinical data related to acromegaly before and after surgery.

NA, not available; HOMA-%, homeostatic model assessment of pancreatic $b$-cell function; HOMA-IR, indicator of insulin resistance. *Significantly less than before surgery, $P < 0.05$.
was 80 (56% of cases). Residual tumors remained in the other four cases. Serum levels of GH were reduced after surgery in all cases (Table 2). The reduction from 155 ± 203 to 3.6 ± 1.7 ng/ml was statistically significant (Table 2). Serum levels of IGF1 were also significantly reduced from 982 ± 98 ng/ml (9.86 ± 0.68 SDS) to 431 ± 276 ng/ml (3.72 ± 3.40 SDS) (Table 2).

Plasma glucose levels were under control after surgery in all cases without requiring insulin therapy. Furthermore, six patients did not need oral hypoglycemic agents after surgery. Fasting plasma glucose levels at the time of the 75 g OGTT were <7 mmol/l. Three cases were treated with metformin at either 500 or 750 mg/day or with sitagliptin at 50 mg/day. The insulinogenic index was 0.59 ± 0.44 (n = 8), HOMA-%β was 80 ± 46, and HOMA-IR was 1.27 ± 0.87 (Table 2).

**Discussion**

We demonstrated that ketoacidosis was the first presenting clinical condition in ~1% of patients with acromegaly in the absence of type 1 DM or previously diagnosed type 2 DM. Thus, acromegaly should be considered when ketoacidosis presents in the presence or absence of type 2 DM. Four of nine cases with ketoacidosis had family histories of DM. Thus, regardless of the presence or absence of clinically apparent DM, in some cases, DM might be a precipitating factor for ketoacidosis in the presence of acromegaly, particularly because acromegaly usually exacerbates insulin resistance.

The average age of patients with ketoacidosis was significantly lower than that of other acromegaly patients. These observations are compatible with previous reports that young, male diabetic patients are more prone to developing ketoacidosis (27, 28).

Previous reports suggested that factors that promote ketoacidosis in acromegaly patients included infection, surgical procedures, cessation of octreotide, and excessive ingestion of sugar-containing soft drinks (21). In the present study, excessive ingestion of sugar-containing soft drinks was a potential precipitating factor in six of nine cases. Patients with so-called soft drink ketosis are usually diagnosed because of negative anti-glutamic acid decarboxylase (GAD) antibodies, a history of excessive ingestion of carbohydrates including soft drinks, and obesity in the presence or absence of type 2 DM. Investigators have speculated that Japanese people are prone to soft drink ketosis because their maximum insulin secretion is not sufficient for the amount that is required for excessive consumption of sugar-containing soft drinks (29, 30, 31). Kobayashi et al. (32) examined young patients with type 2 diabetes who presented with obesity and ketosis at the time of disease onset and found an impaired early-phase insulin response after glucose challenge. Those observations may also be true for Japanese patients who have acromegaly.

As we reported previously (33), normal glucose metabolism was restored in a subset of patients who underwent surgery for acromegaly. In that report (33), we divided acromegaly patients into three groups according to their glucose tolerance before and after surgery. Group I consisted of patients with normal glucose tolerance before surgery. Group II consisted of patients with impaired glucose tolerance before surgery and normal glucose tolerance after surgery. Group III included patients with impaired glucose tolerance before and after surgery. In the present study, the insulinogenic index, which measures early insulin secretion, was 0.59 ± 0.44. Further, HOMA-%β, which is an index of basal insulin secretion, was 80 ± 46 after surgery in patients with histories of ketoacidosis. Both parameters were similar to those observed in postsurgical acromegaly subjects who had impaired glucose metabolism before surgery and normalized glucose metabolism following complete pituitary adenomectomy (33). Thus, intrinsic insulin secretion in the patients presented here seemed to be preserved after surgery. The insulinogenic index is usually calculated to assess the early-phase insulin response after glucose challenge (26). The insulinogenic index was decreased significantly in patients with acromegaly following successful treatment with somatostatin analogs (34). We could provide values for the insulinogenic index only after pituitary surgery. Those values were similar to data reported previously by Giordano et al. (34). C-peptide secretion after the standard mixed-meal tolerance test is another indicator of pancreatic β-cell function. This parameter was reported to be clinically relevant to metabolic derangement in patients with acromegaly (35). However, this information was not available for the present study.

![Figure 1](https://www.eje-online.org)

**Figure 1** Schematic of the possible mechanisms by which metabolic derangement in acromegaly promotes development of ketoacidosis.
As we reported, acromegaly exacerbates insulin resistance. However, some patients could not secrete sufficient insulin to overcome resistance (33). High plasma levels of glucose may reduce insulin secretion from β-cells, producing glucose toxicity. Excessive ingestion of soft drinks may further exacerbate glucose toxicity by impairing appropriate insulin secretion. Coexistence of acromegaly-associated insulin resistance and glucose toxicity due to overconsumption of soft drinks might be critical for the development of ketoacidosis due to deficient insulin action (Fig. 1). Enhancement of lipolysis by GH (36) is caused by loss of insulin activity, leading to increased ketone production by the Randle cycle. An increased level of ketones reduces insulin secretion, eventually leading to ketoacidosis. Thus, GH-mediated lipolysis may also be involved in the development of ketoacidosis in patients with acromegaly (Fig. 1).

In conclusion, our data indicate that ~1% of patients with acromegaly present with ketoacidosis as their first clinical condition. Each of the nine cases discussed here had specific manifestations of acromegaly during initial treatment for ketoacidosis. These findings are clinically significant, as they call attention to the importance of diagnosing acromegaly early.
