Abstract

Objective: Dioxin (polychlorinated dibenzodioxins + polychlorinated dibenzofurans) is one of the most toxic chemical substances known. Although it is suspected to cause endocrine disruption, very few epidemiological studies have been carried out on its effects on human steroid hormones. The aim of this study was to elucidate the association of dioxin exposure with steroid hormone levels in the saliva and serum of Vietnamese women.

Study design: Two areas, namely Phu Cat (hot spot) and Kim Bang (nonexposed area), were selected for the study. The study subjects consisted of 51 and 58 women respectively. Saliva, blood, and breast milk samples were collected from the subjects in both the areas.

Methods: Cortisol, cortisone, DHEA, androstenedione, estrone, and estradiol levels in serum and saliva were determined by liquid chromatography–tandem mass spectrometry; dioxin concentrations in breast milk were measured by gas chromatography–mass spectrometry.

Results: Dioxin concentrations in the breast milk of women from the dioxin hot spot were three to four times higher than those in the breast milk of women from the nonexposed area. Good correlations were found between the levels of six steroid hormones in saliva and those in serum respectively. Salivary and serum cortisol and cortisone levels in women from the dioxin hot spot were significantly higher than those in women from the nonexposed area (P<0.001) and those in all the subjects were positively associated with dioxin concentrations in Vietnamese women (P<0.01).

Conclusion: These results suggest that dioxin influences steroidogenesis in humans. Saliva samples can be used for hormone analysis and are therefore excellent specimens in epidemiological studies.

Introduction

Dioxin is one of the most toxic chemical substances known and is a persistent environmental contaminant. During the Vietnam War (1961–1971), the USA Air Force sprayed over 80 million liters of chemical herbicides on southern battlefields for general defoliation and crop destruction (1). This chemical herbicide was contaminated with highly toxic 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin-TCDD) (1). Kreuzer et al. (2) have estimated that the half-life of dioxin in human adults is 7–11 years. Although the war in Vietnam ended more than 40 years ago, dioxin exposure has continued to affect Vietnamese women, making it essential to study its impact on steroid hormone levels.
ago, dioxin hot spots are still found in and around three former USA airbases (3, 4, 5). TCDD accumulates in the fatty tissues of the body as a result of the lipophilic nature of dioxin (6, 7). As such, studies on dioxin concentrations in lactating mothers are mainly carried out using breast milk. Dioxin concentrations in the breast milk of women in the sprayed areas in Vietnam are still higher than those in the breast milk of women in the nonexposed areas (8).

Some of the adverse effects associated with dioxin exposure may be considerably mediated by alterations in endocrine function (9, 10, 11, 12). There have been a few scientific studies concerning the effect of dioxin exposure on human sex steroid hormones in Seveso residents and chemical industry workers (13, 14). Recently, in an epidemiological study, we have demonstrated that salivary cortisol, cortisone, estradiol (E2), and androstenedione (A-dione) levels in primiparous are related to dioxin concentrations in their breast milk (15, 16, 17).

The aim of this study was to further elucidate the relationship between dioxin exposure and steroid hormone levels in the serum and saliva of Vietnamese mothers by using a larger number of subjects residing in a dioxin hot spot and a nonexposed area. Another aim was to compare salivary steroid hormone levels with serum steroid hormone levels determined by liquid chromatography–tandem mass spectrometry (LC–MS/MS) analysis.

Subject and methods

Study area

Agent Orange/dioxin hot spot ▶ The dioxin hot spot selected was Phu Cat Air Base, where chemical herbicides had been stored and the aircraft used to spray Agent Orange/Dioxin during the Vietnam War had been washed. This site is located in Phu Cat district, Binh Dinh province, and is one of the three dioxin hot spots in South Vietnam. The study subjects were chosen from the population that had been living in and around Phu Cat Air Base after the war. Records show that 17,000 drums of Agent Orange, 9,000 drums of Agent White, and 2,900 drums of Agent Blue had been stored there (18).

Control area ▶ The nonexposed area selected was Kim Bang district, Ha Nam province, in the north of Vietnam, which was not exposed to chemical defoliants during the war and is a rural area that has not been affected by industrial pollution.

Reagents

Cortisol, cortisone, DHEA, A-dione, estrone, and E2 were obtained from Sigma–Aldrich. Estrone-13C4, E2-13C4, and progesterone-13C1 were purchased from Hayashi Chemical Industry Co. Ltd. (Tokyo, Japan). Cortisol-2H4 was obtained from Sigma–Aldrich. Estrone-13C4, E2-13C4, and progesterone-13C1 were purchased from Hayashi Chemical Co. Ltd. (Osaka, Japan). Cortisol-2H4 was obtained from Aska Pharma Medical Co. Ltd. (Kawasaki, Japan). 13C12-1,2,3,4-TCDD and 13C12-1,2,7,8-TCDF were obtained from Wellington Laboratories (Guelph, Ontario, Canada). Picolinic acid, 2-methyl-6-nitrobenzoic acid anhydride, 4-dimethylaminopyridine, pentafluorobenzyl bromide, and 2-fluoro-1-methylpyridinium p-toluenesulfonate were purchased from Tokyo Chemical Industry Co. Ltd. (Tokyo, Japan). Triethylamine

www.eje-online.org
was obtained from Wako Pure Chemical Industries Ltd. (Osaka, Japan). Oasis MAX (60 mg, 3 ml), Bond Elut C18, and InterSep pharm cartridges were purchased from Waters Co. (Milford, MA, USA), Varian (Palo Alto, CA, USA), and GL Science (Tokyo, Japan) respectively.

Reagent A contained picolinic acid (40 mg), 2-methyl-6-nitrobenzoic acid anhydride (40 mg), and dimethylaminopyridine (20 mg)/ml of tetrahydrofuran. Reagent B contained 2% 2-fluoro-1-methylpyridinium p-toluene-sulfonate/ml of dichloromethane.

**Instruments**

The LC–MS/MS system used was as follows: an API 5000 triple-stage quadrupole mass spectrometer (Applied Biosystems, Inc.) connected to an LC-20AD pump and SIL HTC autosampler (Shimadzu, Kyoto, Japan). An electrospray ionization (ESI) ion source device was employed for the analysis of estrone and E2. The column used was Xterra-C-18 (Waters Co.).

An API 4000 triple-stage quadrupole mass spectrometer (Applied Biosystems, MDS Sciex, Toronto, ON, Canada) with an ESI ion source, an Agilent 1100 HPLC system (Agilent Technologies, Waldbronn, Germany), and a PTC pal autosampler (CTC Analytics, Zwingen, Switzerland) were employed for the analysis of neutral steroids. The column used was Cadenza CD-C18 (250×3 mm, with an internal diameter of 3 μm; Imtakt, Kyoto, Japan).

The gas chromatography–mass spectrometry (GC–MS) system used was as follows: a high-resolution mass spectrometer (HRMS; JEOL MSStation-JMS700) equipped with a GC (HP-6890, Hewlett-Packard, Palo Alto, CA, USA). The column used was ENV-SMS with 30 m×0.25 mm ID of 0.25 μm film thickness (Kanto Chemical Co., Inc., Tokyo, Japan).

**Analysis of serum steroids by LC–MS/MS**

The procedure used for the analysis of serum steroids was a modified method of Yamashita et al. (19). Human serum (200 μl) was mixed with purified water to a volume of 1.0 ml and then mixed with 1 ng cortisol-2H4, 100 pg DHEA-2H4, 100 pg progesterone-13C3, 100 pg estrone-13C4, and 100 pg/100 μl E2-13C4 as an internal standard (IS). The samples were extracted with 3 ml ethyl acetate, and the extract was applied onto a Bond Elut C18 cartridge to remove impurities. After the elution of steroid fractions with 80% acetonitrile solution, the residue was allowed to react with reagent A (19, 20). The reaction mixture was then applied onto an InterSep pharm cartridge to remove excess reagents. A part of residue containing picolinoyl derivatives and nonderivative steroids was directly assayed by LC–MS/MS as described by Yamashita et al. (19).

The estimation ions were as follows: cortisol and cortisol-2H4, 468.2/309.2 and 472.2/454.3; cortisone and cortisol-2H4, 468.2/309.2 and 472.2/454.3; DHEA and DHEA-2H4, 394.3/175.1 and 398.1/179.4; A-dione and progesterone-13C3, 287.4/109.0 and 318.3/100.1; estrone and estrone-13C4, 376.1/156.9 and 380/160.8; and E2 and E2-13C4, 483.3/264.0 and 487.2/268.2. The lowest analytical limits for cortisol, cortisone, DHEA, A-dione, estrone, and E2 were 50, 50, 5, 10, 1.0, and 0.5 pg/assay respectively. Both the accuracy and precision were within ±20% of the lowest level in intra- and inter-day assays and both were within ±15% for concentrations other than the lowest concentration.

**Analysis of salivary steroids by LC–MS/MS**

Human saliva (1.0–1.5 ml) was mixed with the IS used in the analysis of serum steroids. The extracts were then applied onto a Bond Elut C18 cartridge to separate the polar steroid fractions (cortisol and cortisone) with 20% acetonitrile solution (2 ml) and nonpolar steroid fractions with 80% acetonitrile solution (3 ml). The nonpolar fraction was applied onto an ion cartridge column prewashed with methanol (3 ml), 0.1 M NaOH (1 ml), and water (3 ml) successively. The nonpolar fraction was separated into a neutral fraction with methanol and an estrogen fraction (estrone and E2) with 1% formic acid–methanol. The organic phase for both the fractions was evaporated to dryness. After derivation of the estrogen fraction with 2% pentafluorobenzyl bromide–acetonitrile (100 μl) and 5% KOH–ethanol solution (50 μl) at 53 °C, the derivatives obtained were further separated into the estrone and E2 derivatives on an InterSep SI cartridge column using 15–50% ethyl acetate–hexane. The estrone-3-pentafluorobenzyl fraction was converted into the estrone-3-pentafluorobenzyl-17-hydrazino-2-methylpyridinium derivative by the method of Higashi (21), whereas the E2-3-pentafluorobenzyl fraction was converted into E2-3-pentafluorobenzyl-17-O-2-pyridinium ether using reagent B (22). Both the derivatives were purified on a Bond Elut C18 cartridge column to remove excess reagents, and the purified estrogen derivatives were mixed with 100 μl of 1% formic acid/methanol/acetonitrile (20:1:1), and a 20 μl aliquot of this solution was used for LC–MS/MS. The neutral fraction was treated according to the picolinic acid method described above for...
serum samples. The fraction obtained was estimated by LC–MS/MS (API 5000). The estimation of steroid hormone was performed by using selected reaction monitoring (SRM) and the transitions used are as follows: cortisol and cortisol$^2$H$_4$, 363.3/121.2 and 367.3/121.2; cortisone and cortisol$^2$H$_4$, 361.2/162.8 and 367.3/121.2; DHEA and DHEA$^2$H$_4$, 394.3/175.1 and 398.1/179.4; A-dione and progesterone$^{13}$C$_6$, 287.4/109.0 and 318.3/100.1; estrone and estrone$^{13}$C$_4$, 556.3/313.1 and 560.3/379.3; E$_2$ and E$_2$$^{13}$C$_4$, 544.2/339.0 and 548.2/343.2.

The lowest analytical limits for cortisol, cortisone, DHEA, A-dione, estrone, and E$_2$ were 50, 50, 2, 10, 0.5, and 0.1 pg/assay respectively. Both the accuracy and precision were within ±20% of the lowest level in intra- and interday assays and both were within ±15% for concentrations other than the lowest concentration.

**GC–MS analysis of dioxin in breast milk**

Breast milk samples were analyzed following a previously reported method (8, 23). After the extraction of fat from 10 g of breast milk, 40–80 pg of 17$^{13}$C$_{12}$-labeled polychlorinated dibenzodioxin (PCDD)/polychlorinated dibenzofuran (PCDF) congeners were added as an IS.

A series of purification steps involving alkali digestion and chromatography on a multi-layer silica gel column and an active carbon-dispersed silica gel column were carried out to separate and collect the PCDDS/PCDFs. The final sample extract was evaporated to dryness under a nitrogen steam and then re-dissolved by addition of 20 μl of nonane containing 40 pg of $^{13}$C$_{12}$-1,2,3,4-TCDD and $^{13}$C$_{12}$-1,2,7,8-TCDF as external standards. Finally, determination was done using a gas chromatograph equipped with a HRMS.

The analysis of dioxin was carried out in the selected ion monitoring mode at a resolution of 10 000, and values that were obtained were converted to toxic equivalents (TEQs) using the World Health Organization toxicity equivalency factors (7, 24).

Quality control and quality assurance were ensured following the guidelines described in the Japanese Industrial Standard (JIS). Eligibilities for the analysis of dioxin were certified using the natural reference powder milk CRM607 provided by the European Commission. The recovery rate was typically in the range of 60–95%, and the detection limits were determined at a signal-to-noise ratio of 3 (S/N=3) on a lipid basis. Values for congener concentrations below the detection limits were set to half the detection limits.

**Statistical analyses**

Data are presented as means ± S.D.s in the case of a normal distribution and as medians (interquartile ranges) for a non-normal distribution. Statistical comparisons of the mean differences were done using Student’s t-test in the case of a normal distribution or the Wilcoxon’s signed-rank test for a non-normal distribution. The significance level was set at $P<0.05$. All the statistical analyses were carried out using the SPSS 12.0 Software, JMP®9 Software package (SAS Institute, Cary, NC, USA), and Microsoft Excel 2010.

**Results**

**Comparison of characteristics of the study subjects from the dioxin hot spot and nonexposed area**

Table 1 summarizes the characteristics, such as age, weight, height, and BMI, of lactating women from the two study areas ($n=109$). The characteristics did not differ significantly between the two areas. Likewise, family income and residence period were similar in both the areas.

**Comparison of hormone levels in mothers from the dioxin hot spot and nonexposed area**

Table 2 summarizes the salivary levels of six steroid hormones (cortisol, cortisone, DHEA, A-dione, estrone, and E$_2$) for all the study subjects ($n=109$) from the dioxin

hot spot and nonexposed area, as determined by LC–MS/MS analysis. Salivary cortisol and cortisone levels were significantly higher in women from the dioxin hot spot than in those from the nonexposed area ($P < 0.001$). There were no significant differences between the two areas for any of the other salivary hormones.

Table 3 summarizes the serum levels of the six steroid hormones in the study subjects from the two areas. Cortisol and cortisone levels were significantly higher in women from the dioxin hot spot than in those from the nonexposed area ($P < 0.001$ and $P < 0.01$ respectively). There were no significant differences in serum DHEA, A-dione, estrone, and E$_2$ levels.

**Comparison of TEQ of dioxin levels in the breast milk of lactating women from the dioxin hot spot and nonexposed area**

The median total TEQ of PCDDs (6.29 pg/g lipid), PCDFs (4.44 pg/g lipid), and total PCDDs + PCDFs (11.04 pg/g lipid) for women in the dioxin hot spot ($n = 51$) was significantly higher than for those in the nonexposed area (PCDDs, 1.87 pg/g lipid; PCDFs, 1.41 pg/g lipid; and total PCDDs + PCDFs, 3.15 pg/g lipid). Specifically, dioxin concentrations in the breast milk of lactating women from the dioxin hot spot were more than three times higher than those in the breast milk of lactating women from the nonexposed area ($P < 0.001$).

**Correlation between steroid hormone levels in saliva or serum and dioxin concentrations in breast milk**

Figure 1 shows the correlations between cortisol and cortisone levels in saliva and dioxin concentrations in the breast milk of study subjects from both the dioxin hot spot and nonexposed area. Significantly positive correlations were found between salivary cortisol and cortisone and breast milk dioxin levels (total PCDDs + PCDFs; $P < 0.001$).

**Correlation between salivary steroid hormones and serum steroid hormones**

We analyzed six kinds of steroid hormones in saliva and serum by LC–MS/MS. Figure 3 shows a significantly positive correlation between cortisol, cortisone, DHEA, estrone, A-dione, and E$_2$ in the serum and those in the saliva of study subjects from both the dioxin hot spot and nonexposed area respectively ($P < 0.001$).

**Discussion**

The region investigated in the present study (Phu Cat) is one of the three major dioxin hot spots in Vietnam.

*Wilcoxon’s signed-rank test.
Indeed, according to Dwernychuk (3, 25), the concentration of TCDD recorded at Phu Cat is 194 pg/g in sediments, and the Hatfield Consultancy (26) has reported that the maximum TCDD level of 236 000 pg/g TCDD in soil taken from the vicinity of Phu Cat is much higher than the internationally recognized standard of 1000 pg/g TCDD in soil.

In this study, we demonstrated that dioxin concentrations in breast milk were three- to fivefold higher in women from the dioxin hot spot than in those from the nonexposed area. This result is consistent with that of our previous study (15). A similar study carried out in Seveso has estimated that TCDD concentrations in females are fivefold higher in an exposed area than in a control area after 30 years (27). These studies suggest that the dioxin burden in humans continues for a long duration after environmental exposure.

Salivary cortisol and cortisone levels were found to be significantly higher in women from the dioxin hot spot than in those from the nonexposed area ($P<0.001$). Furthermore, serum cortisol and cortisone levels were also significantly higher in women from the dioxin hot spot ($P<0.001$ and $P<0.01$ respectively). We have recently carried out a similar study on salivary steroid hormone levels in primiparae in a dioxin hot spot (15, 16, 17). In the present study on lactating women (first, second, or third child), which included a larger number of subjects ($n=109$), significantly higher serum and salivary cortisol and cortisone levels were found in lactating women from the dioxin hot spot (Tables 2 and 3; $P<0.001$).

The relationship between dioxin and hormone levels is linear in the dioxin concentration range of 2–25 pg/g lipid (Figs 1 and 2; $P<0.01$). The adrenal gland is a major accumulation site for lipophilic dioxins and Poly chlorinated biphenyls (PCBs) in the body. Three types of

**Figure 2**

Correlation between cortisol (A) and cortisone (B) levels in serum and dioxin concentrations in breast milk of women from the dioxin hot spot and nonexposed area.
steroid hormones (cortisol, aldosterone, and DHEA) are synthesized in the adrenal gland, and their levels, and therefore ratios, are regulated by adrenocorticotrophin. In this study, cortisol and cortisone levels in both serum and saliva were found to be significantly higher in women from the dioxin hot spot than in those from the nonexposed area, whereas the DHEA levels varied less between women from the two areas. These results clarified one of the aims of the present study. We supposed that women who had abnormal steroid hormone levels would have a higher risk of adrenocortical dysfunction such as hyperglycemia, suppression of immune system, and inhibition of osteoblast function.

In our previous study on 18 primiparae in a dioxin hot spot, in which increased salivary cortisol and cortisone levels were observed, an inverted U-shape was obtained for the TEQ of dioxin levels (15). In the present study carried out in 109 lactating mothers, increased cortisol and cortisone levels were found in serum and saliva. However, the model between steroid hormone and dioxin levels could be fit by a straight line rather than with a nonlinear inverted U-shaped curve. The difference between the findings of the present study and those of the previous study carried out in primiparæ may be due to the inclusion of lactating mothers who had given birth to their first, second, or third child in the present study.

The levels of the other hormones studied in this study (DHEA, A-dione, estrone, and E₂) did not change significantly between the dioxin hot spot and nonexposed area. Our previous study had shown that the mean salivary E₂ or A-dione levels did not differ significantly between the dioxin hot spot and nonexposed area, although the curve between salivary E₂ or A-dione levels and dioxin levels was U-shaped in primiparæ (16). In the Seveso study, men aged 22–31 years had reduced concentrations of sperm and serum E₂, but increased concentrations of follicle-stimulating hormone (FSH), 22 years after exposure. By contrast, men aged 32–39 years had increased total sperm and serum FSH concentrations and reduced E₂ concentrations, compared with those from the control area. Serum testosterone levels did not vary (13). These results suggest that exposure at certain time periods of life may affect the subsequent impact of the exposure. Steroid hormones in serum are categorised into three types: the free type (1–3%), the bioavailable type (30–40%), and the inactive type (50%). A correlation between salivary cortisol and serum free cortisol concentrations has been reported (28). Salivary steroid hormones are known to be excreted in serum in a free form. The total serum cortisol:cortisone ratio is ~3:1, whereas the salivary cortisol:cortisone ratio is ~1:6. There are two main reasons for this marked difference in the cortisol:cortisone ratio between serum and saliva. First, salivary gland membranes contain the enzyme 11β-HSD2, which irreversibly converts cortisol into cortisone as it passes through this membrane. Second, more than 90% of the circulating hormone in human serum is bound to proteins such as corticoid-binding globulin (CBG) and albumin. Cortisone binds to CBG in serum with a tenfold lower affinity than cortisol. Consequently, the proportion of free cortisone in serum is much higher than that of cortisol. These findings are reflected in the salivary steroid levels. We also determined the ratios of free to protein-bound hormones from salivary and serum hormone levels. The ratio of each salivary:serum hormone concentration has been reported (28).
It should be noted that low doses of dioxin also affect immune function (29). Thus, in the study that examined the effects of TCDD on Vietnam War air force veterans, Pavuk et al. (30) found an increase in TSH levels, but no change in tri-iodothyronine (T₃) or free T₃ levels. However, results of the studies on endocrine disruption by chemicals can be difficult to interpret and are readily misinterpreted, thus meaning that the same factor could stimulate or inhibit (31).

We found a strongly positive correlation between salivary hormones and serum hormones \((P<0.001;\) see Fig. 3). We chose saliva as the matrix for steroid hormone analysis in this study as it is noninvasive and easy to collect from subjects, even from children, and is feasible for use in epidemiological studies.

LC–MS/MS is an excellent technique with higher sensitivity and accuracy than standard immunoassay methods. Furthermore, this technique can also be used to simultaneously analyze six steroids, including those, such as cortisol and cortisone, with a similar molecular structure using only 0.1 ml of serum. We also established an analytical method for \(E_2\) involving chemical derivatization that allows even trace amounts to be detected. This method has a limit of quantification of 0.1 pg/ml by LC–MS/MS.

There are some limitations to this study. The study subjects were women \((n=109)\) who had given birth up to 1 year before the study and therefore may have returned to a normal menstrual cycle with the physiological activity inherent to normal hormone regulation (32). Therefore, it is probably difficult to determine the levels of sex hormones, such as progesterone and estrogen, in women with varying menstrual cycles.

In summary, the relationship between dioxin exposure and endocrine disruption requires further clarification to be able to evaluate adverse human health effects caused by dioxin and/or other environmental chemicals. It is especially important to continuously monitor the health of mothers throughout life and to investigate any possible influence on the development of their children at dioxin hot spots in Vietnam.
