Abstract

Objective: Glucocorticoids stimulate several steps in red blood cell (RBC) development; however, little is known on changes in erythroid parameters in patients with Cushing’s disease. The aim of this study was to assess both RBC and white blood cell (WBC) parameters in a large cohort of patients with Cushing’s disease and report on alterations in the active phase and after surgical remission.

Design and methods: A total of 80 patients with Cushing’s disease (63 women and 17 men) were studied before and for up to 254 months’ follow-up (mean follow-up 65.8 ± 6.71 months) after pituitary/adrenal surgery. Details of blood counts were reviewed and compared with data obtained from a database of healthy subjects.

Results: The RBC counts and haemoglobin levels were low in men with active Cushing’s disease (over 80% of values in the lowest quartile) and four patients were overtly anaemic, whereas erythrocyte counts and haemoglobin levels were evenly distributed across the normal range in women with active Cushing’s disease. Low erythroid parameters were linked to hypogonadism in men with Cushing’s disease. Recovery in erythroid parameters occurred slowly after remission of hypercortisolism in men, in parallel with improvements in testosterone levels. Over 50% of patients with active disease presented increased WBC counts, irrespective of gender, and prompt normalisation within 1 month after surgery.

Conclusions: Male patients with Cushing’s disease present reduced RBC counts and haemoglobin levels, associated with low testosterone concentrations, which resolve over time after remission of hypercortisolism. Anaemia should therefore be regarded as another unfavourable feature in men with Cushing’s disease.

Introduction

Cushing’s syndrome presents with protean clinical manifestations due to the manifold consequences of excess cortisol secretion. However, while some features of hypercortisolism, for example osteoporosis or diabetes, are well known and have been extensively investigated, others remain to be fully characterised. One feature which has been little studied is altered haematopoiesis, although glucocorticoids are known to be important modulators of several crucial steps of red blood cell (RBC) development. In fact, glucocorticoids enhance proliferation of erythroid progenitor cells and participate in stress erythropoiesis following hypoxia or blood loss (1, 2, 3, 4). In clinical settings, glucocorticoids have been administered since the 1950s to patients with inherited RBC aplasias, such as Diamond–Blackfan anaemia (5), and to ameliorate anaemia in myeloproliferative disorders (6).

Historically, patients with Cushing’s syndrome are often described as polycythaemic and pethoric and, indeed, ‘round, red face’ is a common description. Harvey Cushing reported that his first patient, Minnie G.,
presented 5.30×10^{12}/l erythrocytes and bright mucosae notwithstanding frequent nose and bowel bleedings (7). More recently, polycythaemia was the presenting feature in two patients with Cushing’s disease (8, 9). However, a thorough evaluation of RBC counts in patients with Cushing’s syndrome and their course after remission of hypercortisolism is yet to be performed. This feature is of particular interest given that RBC counts as well as Cushing’s disease present gender-related features. RBC mass is greater in men than in women due to the effects of testosterone on erythropoiesis (10, 11) and, further, women of childbearing age, the age frame of Cushing’s disease, often present slight anaemia due to menstrual blood losses. Conversely, although Cushing’s disease is more prevalent in women than in men, several features of hypercortisolism are more severe in men than in women (12), suggesting a role for gonadal hormones. We therefore decided to analyse haematological alterations in men and women with Cushing’s disease, both in the active disease phase and after cure.

**Subjects and methods**

The study population comprised 80 patients with Cushing’s disease, 63 women and 17 men; age range between 15 and 62 years; mean 39.1 ± 1.15 years. Diagnosis of Cushing’s syndrome was established according to standard diagnostic criteria (13, 14) and confirmed by pathology on transsphenoidal surgery specimens. Sixty-one patients were re-evaluated after remission of hypercortisolism: in 46 patients remission resulted from transsphenoidal surgery and in 15 patients from adrenalectomy (carried out as first-line surgery or after unsuccessful transsphenoidal surgery). The course of haematological parameters after unsuccessful pituitary surgery was evaluated in 16 patients. Corticosteroid replacement therapy was administered after transsphenoidal surgery starting at 25–37.5 mg cortisol acetate daily and then tapered over the following 1–71 months (mean length of treatment 16.37±2.11 months). Neither men nor women were on gonadal steroid replacement therapy. Mean follow-up after surgery was 65.8±6.71 months, range 7–254 months. Blood sampling was carried out shortly after surgery (i.e. 1–2 weeks) in all patients; patients in remission were re-evaluated every 2–3 months until full recovery of the pituitary–adrenal axis and then yearly once off steroid replacement therapy. Where available, results of testing for growth hormone (GH) reserve by means of GH-releasing hormone (GHRH)+arginine stimulation test were included (i.e. GH deficient if GH peak <9µg/l) (15). Patients with persistent hypercortisolism after surgery were re-evaluated every 3–4 months until repeat pituitary surgery or adrenalectomy, radiotherapy or medical therapy. No patient was taking iron, vitamin B12 or folate supplementation and none referred piles or gastric ulcer. Informed consent was obtained from all patients for review of clinical charts and the study was approved by the Local Ethical Committee.

We reviewed blood cell counts, in particular, RBC count, haemoglobin and mean corpuscular volume (MCV) values, white blood cell (WBC) count and percentage of neutrophils and eosinophils. Standard blood chemistry tests, e.g. fasting blood glucose, electrolytes, total protein and cholinesterase, as well as hormonal parameter measurements, i.e. plasma adrenocorticotropic hormone (ACTH) and serum cortisol, serum cortisol after 1 mg dexamethasone overnight (i.e. OST), gonadal hormones (i.e. follicle-stimulating hormone, luteinizing hormone, total testosterone, 17β-oestradiol, progesterone), thyroid-stimulating hormone and free thyroid hormones, had been performed on early morning serum/plasma samples after an overnight fast. Urinary free cortisol (UFC) was averaged over three 24-h urine collections. Review of laboratory indices of infections, e.g. elevated C-reactive protein, erythrocyte sedimentation rate, was carried out in order to exclude concurrent infection; blood cell counts were measured from a single blood sample at each evaluation.

**Assays**

Clinical chemistry platform was used to determine routine clinical analytes (Hitachi 917, Roche Diagnostics). Haematology was performed on Unicel DxH Coulter Cellular Analysis System (Beckman Coulter, Inc., Cassina de’ Pecchi, Italy). Normal ranges for RBC and WBC parameters are haemoglobin 13.8–18.0 g/dl, RBC count 4.5–5.5×10^{12}/l for men and haemoglobin 11.9–16 g/dl, RBC count 4.10–10.5×10^{12}/l for women, MCV 80–96 fl, WBC count 4.3–10.5×10^{9}/l, neutrophils 40–75% and eosinophils <6%. Control data for haematological analyses were obtained from a database of over 3000 healthy normal subjects collected at our centre.

Serum cortisol was measured using radioimmunometric Coat-a-Count assay (Diagnostic Products Corp., Los Angeles CA, USA) and the same assay was used for UFC after extraction of dichloromethane; plasma ACTH was quantified by immunometric chemiluminescent assay (Elecsys, Roche Diagnostics). Normal ranges are 27.6–220.7 nmol/24 h for UFC, 138–689 nmol/l for...
serum cortisol and 2.2–11 pmol/l for ACTH. Total testosterone and other hormones were assayed by electrochemiluminescence (ECLI A, Roche Diagnostics). Total testosterone concentrations <9.9 nmol/l were used as the criterion for the diagnosis of hypogonadism in adult men (16).

**Statistical analysis**

Mann–Whitney U or Wilcoxon test were used for quantitative analyses, as appropriate; \( \chi^2 \) or Fisher’s exact tests for analysis of qualitative data. The association between variables was tested by linear correlation. The comparisons yielding \( P < 0.05 \) were considered significant. Values are expressed as mean ± S.E.M.

**Results**

**Active Cushing’s disease**

Men with Cushing’s disease presented RBC parameters in the low–normal range and four patients were frankly anaemic (17). Distribution of values was significantly skewed compared with normative data with 81% of patients presenting values in the lowest haemoglobin quartile (i.e. <14.7 g/dl) and 87.5% of patients with RBC counts in the lowest quartile (i.e. <4.81 \( \times 10^{12} \) l; Fig. 1). Mean haemoglobin and RBC values in men with Cushing’s disease were significantly lower than in healthy subjects (14.45 ± 0.21 vs 15.28 ± 0.34 g/dl and 4.47 ± 0.13 vs 5.06 ± 0.13 \( \times 10^{12} \) l respectively, both comparisons \( P < 0.001 \)). MCV was increased in men with Cushing’s disease (93.21 ± 0.87 vs 89.38 ± 0.17 fl, \( P < 0.005 \)) and 50% of patients presented values in the upper quartile of the normal range (i.e. >96.3 fl).

Conversely, RBC counts were evenly distributed across the normal range in women with Cushing’s disease with only a slight, non-significant increase in the proportion of patients in the upper quartile (36.5% of patients with haemoglobin >16.6 g/dl; 33% with RBC >6.67 \( \times 10^{12} \) l). In keeping, mean haemoglobin levels in women with Cushing’s disease were marginally higher than in controls (13.75 ± 0.17 vs 13.16 ± 0.25 g/dl, \( P < 0.05 \)), whereas RBC counts were superimposable (4.52 ± 0.65 vs 4.40 ± 0.01 \( \times 10^{12} \) l, NS; Fig. 1). MCV was uniformly distributed across the normal range in women with Cushing’s disease and average values were superimposable to the healthy population (90.27 ± 1.11 vs 89.38 ± 0.17 fl, NS). Erythroid parameters were evaluated according to menstrual status in women with Cushing’s disease, but no significant trend was observed (mean haemoglobin 13.2 ± 0.28, 13.83 ± 0.35, 14.05 ± 0.35 and 14.09 ± 0.57 g/dl in women with amenorrhoea, oligomenorrhoea, polimenorrhoea and normal menses respectively, NS).

No significant correlation was detected between RBC parameters and hypothalamic–pituitary–adrenal axis or thyroid function in either sex (data provided in

---

**Figure 1**

Red blood cell (RBC) counts and haemoglobin levels in female and male patients with active Cushing’s disease. Normal range is represented by the grey area, dotted lines indicate 1st and 3rd quartiles, dashed line indicates median in healthy control population.
Supplementary Table 1, see section on supplementary data given at the end of this article). Conversely, a significant correlation was detected between RBC parameters and testosterone levels in men with Cushing’s disease ($r=0.69$, $P<0.05$ and $r=0.55$, $P<0.05$ for RBC and haemoglobin levels respectively). In fact, hypogonadism was diagnosed in all but three male patients (81%; average total testosterone $7.59\pm0.82$ nmol/l). No correlation was detected between testosterone levels and RBC or haemoglobin levels in women with Cushing’s disease ($r=-0.05$, NS and $r=0.01$, NS respectively). Of note, only two women with active Cushing’s disease presented increased testosterone levels (i.e. $>2.86$ nmol/l).

As expected, distribution of WBC counts was slanted towards the upper quartile of the normal range (i.e. $>8.05\times10^9$/l), 52% of patients presented with counts above the normal range and 22 patients (32%) with frank leukocytosis (i.e. $>11.5\times10^9$/l; Fig. 2). Not surprisingly, mean WBC counts were higher in patients with Cushing’s disease than in normal subjects ($9.56\pm0.31$ vs $7.39\pm0.04\times10^9$/l, $P<0.001$). No correlation was detected between WBC and UFC and other parameters of HPA activity (data provided in Supplementary Table 2, see section on supplementary data given at the end of this article). Reciprocal changes in the neutrophil and eosinophil populations were observed in patients with Cushing’s disease, with 73% of patients presenting neutrophil percentages in the upper quartile of the normal range (i.e. $>63.7\%$) and 27% frank neutrophilia (i.e. $>75\%$ neutrophils). Mean neutrophil proportion was higher in patients with Cushing’s disease than in controls ($68.24\pm1.18$ vs $57.03\pm0.18\%$, $P<0.001$ respectively). Conversely, average eosinophil percentage was lower in patients than in healthy subjects ($1.35\pm0.18$ vs $2.86\pm0.04\%$, $P<0.001$) and distribution skewed towards the lowest quartile (71% of patients with eosinophils $<1.5\%$).

Remission of hypercortisolism and persistent Cushing’s disease

A reduction in haemoglobin levels by 1.5–2 g/dl was observed in both sexes within the first 2 weeks after pituitary surgery, regardless of its outcome, and levels fell to $12.5\pm0.18$ g/dl in women and $12.6\pm0.45$ g/dl in men (both comparisons $P<0.001$ compared with pre-surgery values). After surgery, men were again more anaemic than women (68% of men vs 18% women, $P=0.0036$ by Fisher’s exact test). In keeping, normalisation of haemoglobin values after remission of Cushing’s disease occurred within 1 year in women ($\sim25\%$ of measurements in each quartile 16 months after surgery), whereas slower recovery was observed in men with over 20% still presenting haemoglobin values below the normal range at the same time point (Fig. 3). Indeed, quartile distribution of haemoglobin values approached control distribution after $>2$ years in men in remission. Testosterone levels also increased slowly after surgery in men in remission and achieved full normalisation on average 24 months after surgery (Fig. 4). RBC counts were positively correlated with testosterone levels after successful surgery in male patients with Cushing’s disease ($r=0.349$, $P<0.05$) (Fig. 4). No impact of corticosteroid replacement therapy was observed on changes in RBC parameters. Of note, no patient was on testosterone replacement therapy. Assessment of GH status was available in 37 patients and revealed GH deficiency, i.e. GH peak $<9 \mu g/l$ after GHRH+arginine, in 16 out of 24 women and all 13 men, 2 years after surgery.

The MCV decreased significantly 3 months after surgery in both women and men ($86.7\pm0.99$ and $87.7\pm1.05$ fl respectively, $P<0.005$ vs pre-surgical values) and 12% of patients presented low MCV, in keeping with post-surgical blood loss and average RBC lifespan. MCV progressively normalised over the following months and was superimposable to pre-surgical values 1 year after surgery ($87.8\pm0.98$ and $88.7\pm0.74$ fl in women and men respectively).

WBC counts fell significantly within 4 weeks after surgery ($9.56\pm0.31$ vs $8.3\pm0.398\times10^9$/l, $P<0.005$) in
patients in remission from Cushing’s disease and thereupon the values continued to decrease (7.12 ± 0.415 × 10^9/l at 1 year and 6.18 ± 0.274 × 10^9/l at 2 years after surgery). Reduction in WBC counts was associated with a reduction in neutrophils, as the mean percentage decreased from 68 to 58% (P < 0.005) within the first month. Three months after surgery, 94% of patients in remission presented normal WBC and neutrophils. At the same time, percentage of eosinophils increased from 1.3 to 2.7% (P < 0.005). In contrast and not surprisingly, no significant differences were observed in WBC, neutrophils and eosinophils before and after surgery in patients with persistent hypercortisolism.

Discussion

The relationship between glucocorticoids and erythropoiesis is well-known and long standing, as documented by both experimental data and clinical experience. In fact, extensive in vitro studies have shown that glucocorticoids potentiate erythropoiesis (4, 18), enhance proliferation and self-renewal of erythroid progenitors (1), stimulate erythropoietin (19) and cooperate with its effects on progenitor cells (20, 21). Further, glucocorticoids are essential to stress erythropoiesis as glucocorticoid receptor-deficient mice are unable to mount an adequate erythroid response to hypoxia or blood loss, both in terms of erythroid-colony

Normal ranges are represented by the grey area.
Our study is the first to report on RBC parameters in a large series of patients with Cushing’s disease, thus exploring changes in the erythroid compartment occurring during long-term exposure to excess cortisol levels. Our findings indicate that changes are clearly gender-dependent, with men with Cushing’s disease presenting low-normal RBC counts and haemoglobin concentration and women, on the contrary, presenting normal, if slightly above average peripheral erythroid cell counts. This distribution is the reversal of RBC parameters in the normal population and substantiates findings reported in a small group of patients with Cushing’s disease (9).

Common causes of anaemia, e.g. piles, gastric ulcer, intestinal bleeding, were not prevalent in either sex and are unlikely to contribute to the current finding as they would conceivably affect men and women with Cushing’s disease in an equal manner. Still, the possibility of men with Cushing’s disease presenting a greater prevalence of mild blood gastrointestinal loss cannot be excluded and warrants a thorough investigation, i.e. endoscopy, faecal occult blood testing, in future studies. Interestingly, cessation or dwindling of menses was not associated with changes in erythroid parameters, thus menstrual blood loss does not appear to contribute significantly to RBC mass in women with Cushing’s disease.

Altogether, this suggests that women with endogenous hypercortisolism are sensitive to the erythroid expansive effect of corticosteroids and may explain the fact that – as the wide majority of patients with Cushing’s disease is female – patients are commonly referred to as ‘ruddy cheeked’. Conversely, factors other than cortisol excess per se modulate the erythroid compartment in men with Cushing’s disease and one likely culprit is hypogonadism. Low testosterone is a very common sign of Cushing’s syndrome in men (22, 23) due to the known inhibitory effect of excess cortisol on the hypothalamo-pituitary-gonadal axis. On the other hand, testosterone is an important determinant of erythropoiesis and contributes to the gender-related differences in erythroid parameters in adults (10). Further, administration of testosterone to hypogonadal men leads to a marked increase in haemoglobin level (24, 25) through a variety of effects on erythroid precursor cells, iron absorption and, possibly, erythropoietin synthesis (11). In our series, testosterone levels were mostly decreased in patients with Cushing’s disease and strongly correlated with both haemoglobin and RBC counts, thus pointing to a direct link between low testosterone levels and low RBC parameters. This link was also evident in the postoperative recovery phase, as both testosterone and erythroid parameters normalised slowly and in a parallel fashion. These findings support the contention that testosterone – rather than excess cortisol – modulates RBC mass in men with Cushing’s disease. Another hormone known to modulate erythroid proliferation is GH and, indeed, GH/insulin-like growth factor 1 (IGF1) are involved in proliferation and maturation of erythroid progenitors (26). In keeping, erythropoiesis may be impaired in patients with GH deficiency (27) and haemoglobin levels, reticulocyte counts and erythropoietin concentrations increase on replacement therapy with rhGH (28, 29).

Patients with Cushing’s disease are notably GH deficient (30, 31) and we had previously reported that defects in the GH–IGF1 axis are more persistent in men in remission after transphenoidal surgery (15), possibly again connected to persistent hypogonadism. In fact, all male patients tested for GH deficiency after surgery were GH deficient compared with only 2/3 of women in remission.

This study highlights yet another difference in the clinical presentation between male and female patients with Cushing’s disease. We had first reported that men with this disorder display a more severe clinical presentation than their female counterparts some 10 years ago (12) and our findings have since been confirmed by other investigators (32, 33). Of interest, some of the more severe clinical features in men, e.g. osteoporosis and vertebral fractures, can clearly be connected to low testosterone secretion (34).

This study was aimed at exploring possible derangements of erythroid cells in patients with Cushing’s disease and thus comprised the most relevant parameters, as assessed by standard haematology coulter analysis. Our results pave the way to further in-depth evaluations of RBC homoeostasis, including iron, folate or vitamin B12 deficiency, reticulocyte counts and erythroid lifespan, in order to canvass features of anaemia in male patients with Cushing’s disease and lead to targeted therapeutical approaches.

In contrast to erythroid cells, no gender-related differences were observed in the expected increase in WBC. Higher cortisol levels are associated with higher WBC and neutrophil counts in several conditions, e.g. ischaemic stroke, labour and exercise-related stress, although a significant correlation between these variables
Anaemia in men with Cushing’s disease

could not always be demonstrated (35). On the other hand, testosterone plays a minor role in the modulation of WBC (36). Leukocyte counts and percentages of neutrophils and eosinophils were normalised promptly after remission of hypercortisolism in patients with leukocytosis in the active phase, thus proving a good marker for cure in these patients.

In conclusion, we observed significant gender-dependent differences in this first large-scale study on erythroid status in patients with Cushing’s disease. Men with Cushing’s disease present low RBC and haemoglobin levels, are frequently anaemic and require a lengthy recovery prior to normalisation of erythroid parameters after remission of hypercortisolism. These changes were associated with low testosterone levels both in the active phase and after remission. Conversely, women with Cushing’s disease are slightly polycythaemic, independent of menstrual status. Close monitoring and further studies are warranted in order to further define its characteristics.
