Abstract

Objective: To assess thyroid function, the presence of thyroid antibodies, as well as the presence of goiter and/or nodules in subjects without a prior diagnosis of thyroid disorders, in a region with mild to moderate iodine deficiency.

Design and methods: This cross-sectional study is based on data obtained from first and third visits of participants in the Sardinian survey. We performed two different analyses. In one, we assessed the prevalence of unknown thyroid dysfunctions among 6252 subjects who had a medical examination and blood collection for assays of thyrotropin, free thyroxine, and antibodies against thyroperoxidase (AbTPO) and against thyroglobulin (AbTG). In a second analysis, we evaluated the frequency of undiagnosed goiter and nodules among 3377 subjects who had a thyroid ultrasound scan. Subjects were excluded if they had a previous history of thyroid disorders or presence of goiter and/or nodules, or thyroid surgery, or if they were taking drugs that could impair thyroid function.

Results: We found a low prevalence of overt thyroid dysfunction (hyperthyroidism 0.4% and hypothyroidism 0.7%). The rates of subclinical hypothyroidism and hyperthyroidism were 4.7 and 2.4% respectively. Almost 16% of participants were positive for at least one antibody and 5.2% for both AbTG and AbTPO. Nodules were detected in 17.4% of subjects and the prevalence of goiter was 22.1%.

Conclusions: Undiagnosed biochemical thyroid dysfunctions, unknown nodules, and goiter were common in subjects living in a mild to moderate iodine-deficient area. In this community, thyroid disorders often go undetected and screening could be reasonable in subjects at a higher risk.

European Journal of
Endocrinology
(2014) 171, 143–149

Introduction

Thyroid disorders are one of the most frequent pathologies found in the general population, but identifying thyroid disease can be clinically challenging because subclinical thyroid dysfunction and autoimmune thyroiditis are often asymptomatic and usually diagnosed biochemically. Abnormal thyroid function has important public health consequences. Suppressed thyroid stimulating hormone (TSH) levels have been associated with an increased risk of atrial fibrillation, premature atrial beats, and stroke, and all cause mortality (1, 2, 3). In addition, suppressed TSH levels have been associated with a decreased bone density (4).

Moreover, overt hypothyroidism contributes to elevated serum LDL cholesterol levels and is a risk factor for coronary heart disease, heart failure, and atherosclerosis (5, 6). Some studies also suggest that this may also be true in patients with subclinical hypothyroidism (7). Most epidemiological surveys have reported the biochemical aspects of thyroid disorders, although with different results. The difficulties for determinations and their comparison arise from the variable definitions of disease state, the heterogeneity of the populations studied, the range of normality of biochemical parameters, and the sensitivity of thyroid

function tests used. For example, the introduction of assays for serum TSH sensitive enough to distinguish between normal and low concentrations allowed the identification of subjects with subclinical hyperthyroidism. Additional variables include genetic (8, 9) and environmental factors, such as iodine intake (10, 11). Indeed, almost one-third of the world's population lives in areas of iodine deficiency (12), and the prevalence of goiter can be as high as 80%. The introduction of ultrasonography in epidemiological studies has increased the diagnostic power to assess the presence of goiter and/or nodules in comparison with studies in which goiter was assessed by physical examination (13). In this study, a large cohort provided a unique opportunity to conduct a cross-sectional study of abnormal thyroid function and morphology. We assess both the prevalence of abnormal biochemical thyroid disease and the frequency of nodules and goiter in subjects without known thyroid abnormalities.

Materials and methods

The SardiNIA study investigates more than 300 genotypic and phenotypic aging-related traits in a longitudinal survey. The main features of this project have been described in more detail previously (14). All residents from four towns (Lanusei, Arzana, Ilbono, and Elini) in a valley in Sardinia (Italy) were invited to participate. Since November 2001, participants had visited and their blood samples analyzed about every 3 years, generating three complete surveys, and some new subjects were progressively enrolled to complete family units.

We performed two analyses. In one, we analyzed the frequency of biochemical thyroid disorders, including all subjects who had a medical examination at the first time in the first or third visit waves. (We did not include participants from the second survey because TSH was the only parameter checked at that visit.) We excluded all subjects with self-reported thyroid disease (i.e. Hashimoto's thyroiditis, hyperthyroidism, or hypothyroidism) and those taking drugs impairing thyroid function (levothyroxine, thyrostatics, amiodarone, and carbolithium). The final cohort included 6252 participants (female, 54.8%) aged 14–102 years. A second analysis was performed to observe the prevalence of undiagnosed thyroid nodules and goiter. We assessed all subjects in whom thyroid ultrasound was carried out during the third visit wave. Subjects who reported thyroid nodules, goiter, or thyroid surgery were excluded, yielding a final sample of 3377 participants (female, 52.4%). The iodine status at the time of evaluation was not assessed. However, the data

on urinary iodine excretion of subjects living in this area was obtained from a study by Martino *et al.* (15), showing a mild to moderate iodine deficiency.

Biochemical and hormone assays

Blood venous samples were drawn between 0700 and 0800 h after an overnight fast. Serum samples were assayed for TSH, free thyroxine (FT₄), and antibodies against thyroperoxidase (AbTPO) and against thyroglobulin (AbTG) using an automated chemiluminescence assay system (Immulite 2000, Erlangen, Germany). The method is a two-site, solid-phase chemiluminescent immunometric assay. Normal values are as follows: TSH, 0.4–4.0 µIU/ml; FT₄, 0.89–1.76 ng/dl; AbTPO, <35 IU/ml; and AbTG, <40 IU/ml.

Overt hypothyroidism was defined as a serum TSH level above the upper limit of the reference range and serum FT₄ level below the lower limit of the reference range. Overt hyperthyroidism was defined as serum TSH levels below the lower limit of the reference range and serum FT₄ level above the upper limit of the reference range. We defined subclinical thyroid dysfunction as serum FT₄ levels in the normal reference range together with high serum TSH (subclinical hypothyroidism) or low serum TSH (subclinical hyperthyroidism) level.

Thyroid ultrasound

Conventional thyroid ultrasound was performed with a real-time instrument (ATL 3500 HDI machine with a linear transducer 5–12 MHz). Subjects were supine, with neck hyperextended. A nodule was defined as the presence of any distinct lesion within the thyroid gland detected by ultrasound, regardless of the echoic pattern. Subjects with nodules were divided into two categories: 'solitary nodule' if only one nodule was detected, and 'two or more nodules' (otherwise defined 'multiple'), if the ultrasound scan revealed the presence of at least two nodules. Thyroid volume was calculated according to the ellipsoid model (16). Goiter was

defined as a thyroid volume exceeding 13 ml in women and 18.1 ml in men (17), regardless of the presence of nodules.

Each participant signed an informed consent form. All study methods were conducted according to the principles laid down in the Declaration of Helsinki and were approved by the governing Ethics Committee, ASL4.

Statistical analysis

Results are expressed as median and interquartile range. Statistical differences in frequencies were tested by the Fisher's exact test in Stata 12.0 for Macintosh. Significance was set at $P < 0.05$.

Results

Biochemical thyroid dysfunctions

The baseline characteristics of the subjects are given in Table 1. Overt hypothyroidism and hyperthyroidism were diagnosed in 42 (0.7%) and 23 (0.4%) participants respectively. Subclinical hypothyroidism was found in 293 (4.7%) subjects, whereas subclinical hyperthyroidism was detected in 152 (2.4%) subjects. The prevalence of thyroid dysfunctions progressively increased with age, to reach a maximum of 13.9% in subjects older than 80 (Table 2). The distribution of AbTPO and AbTG across age groups is shown in Fig. 1. Table 3 displayed the frequency of AbTPO and AbTG across thyroid dysfunctions. The frequency of thyroid antibodies was higher in women than in men ($P < 0.001$), when considering the presence of at least one antibody (20.9 vs 9.9%), when detected both together (6.9 vs 3.1%), as shown in Table 4. Among the whole sample studied, 1307 (20.9%) participants had at least one biochemical thyroid disorder: 313 had hyper- or hypo-function of the gland without detectable thyroid antibodies, 797 showed only the positivity of at least one

antibody, and 197 had a thyroid dysfunction associated with at least one circulating antibody.

Thyroid nodules and goiter

The second analysis included 3377 subjects in whom thyroid ultrasound was performed during the third survey. Among them, 588 (17.4%) showed the presence of nodularity: 232 had a solitary nodule and 356 had at least two nodules. The presence of undiagnosed thyroid nodules progressively increased with aging, with the highest prevalence in subjects aged 80 years or older (31.6%, Fig. 2). The presence of nodules (solitary or multiple) was associated with thyroid antibodies (AbTPO and/or AbTG) in 19% of subjects. The overall prevalence of goiter was 22.1% and this progressively increased with aging, as reported in Fig. 2. It was observed in 748 subjects, among whom 99 (13.2%) had a solitary nodule, 106

(14.2%) had multiple nodules, and 543 (72.6%) did not show nodularity. Females had a higher frequency of nodularity than males ($P < 0.001$, Table 5) (for solitary nodule, 8.0 vs 5.6%; for multiple nodules, 11.2 vs 9.8%), while the prevalence of goiter was increased in males (26.1 vs 18.5%, $P < 0.001$), as reported in Table 5.

Discussion

Although thyroid dysfunction has multiple implications for public health, the magnitude of the problem is not completely known, nor is the relationship to other thyroid alterations well delineated. Our large population-based study in an area with mild to moderate iodine deficiency provides comprehensive data on the prevalence of unknown thyroid dysfunctions, autoimmune thyroid disorders, and unknown thyroid nodularity and goiter.

Overt hyperthyroidism was found in 0.4% (23/6252) of the sample. This finding is somewhat higher than those

described in Norway (18) and in the Colorado Study (19), but similar to those reported by Volzke in Germany (20). The prevalence of unknown subclinical hyperthyroidism was 2.4%. These findings were again lower than those reported in some studies (17), but higher than others (20, 21, 22, 23). Differences between studies may reflect different age ranges of cohorts and other environmental factors. Particularly important is the local iodine level. For example, a higher prevalence of hyperthyroidism due to an increased frequency of toxic nodular goiter has been documented in an iodine-deficient community (17), and subclinical hyperthyroidism was also more frequent in an iodine-deficient area compared with an iodine-replete area (17, 20, 22). Our survey showed a prevalence of hyperthyroidism, which is somewhere between the prevalence reported in iodine-deficient areas and iodine-replete areas, and consistent with the mild to moderate iodine deficiency in this area. However, we cannot differentiate the type of hyperthyroidism because we did not assess antibodies against TSH receptor.

Figure 2

Prevalence of nodules and goiter across age groups.

The prevalence of overt hypothyroidism was 0.7% (42/6252), with a higher frequency in females (71.4%) than in males (28.6%). This prevalence is similar to that reported by Volzke *et al.* (20) but higher than that reported by Aghini-Lombardi *et al.* (17) in another survey in Italy and by Lucas *et al.* (21) in Spain. Moreover, we found unknown subclinical hypothyroidism in 4.7% of subjects, which is substantially higher than that reported previously.

In this study, the prevalence of thyroid antibodies (AbTPO, AbTG, or both) was 15.9%, which is higher than that reported in previous studies. However, whether or not iodine intake influences the development of thyroid autoimmunity remains controversial. Indeed, both low and high iodine intake have been associated with an increased tendency toward thyroid autoimmune abnormalities (10, 24, 25). According to some authors, the development of goiter due to iodine deficiency might overexpose the immune system to thyroid antigens, leading to immune reactions (26, 27). Assuming that iodine intake might interfere with the thyroid autoimmune process, only genetically predisposed subjects would present the disease (28). In keeping with this hypothesis, our data are consistent with a very high incidence of autoimmune diseases such as chronic autoimmune thyroiditis, type 1 diabetes mellitus, and multiple sclerosis in the Sardinian population (29). The prevalence of thyroid dysfunctions linked to the presence of AbTPO and/or AbTG ranged from 73.8% in subjects with overt hypothyroidism to 17.1% in those with subclinical hyperthyroidism (Table 3). Moreover, 13.9% of subjects with euthyroidism had circulating thyroid antibodies. These data are in line with previous findings that overt and subclinical hypothyroidism generally are

autoimmune, whereas subclinical hyperthyroidism is usually related to multinodular goiter, with relatively frequent detection of serum thyroid antibodies, especially in goitrous females (17, 26, 30, 31) and in older subjects, as confirmed in our analysis.

The second analysis included 3377 patients who underwent thyroid ultrasound. We found 588 subjects (17.4%) with unknown thyroid nodules, 232 with solitary nodules, and 356 with at least two nodules. These findings are comparable to those reported by other authors (20). The prevalence of thyroid nodules increased with age up to 80 years and above (31.6%).

Age and sex distributions were similar to those observed in previous reports in moderate iodine-deficient areas, with a progressive increased prevalence of goiter in older subjects, though the prevalence of goiter was rather lower than that reported by Martino *et al.* (15) in the same geographic area. Different methods of estimation may account for this difference.

One exclusion criterion was self-reported patient data for previous diagnosis of thyroid disease and/or medications. Hence, all the data should be analyzed with some reservations about possible undercounting, but the results of our analysis are consistent with previous reports.

A major finding of our study was a 20.9% (1307/6252) prevalence of undiagnosed biochemical abnormalities of the thyroid gland. In this group, 313 subjects (23.9%) had thyroid dysfunction, and the positivity of thyroid antibodies was found in 797 subjects (61%), whereas thyroid dysfunction together with circulating antibodies were found in 197 participants (15.1%). Our study indicates that the prevalence of thyroid dysfunction and/or abnormal thyroid anatomy is rather frequent in an unselected population living in this mild to moderate iodine-deficient region. Although in this study the demographic characteristics of the population studied may not be completely generalizable, we provide

Table 5 Frequency of goiter and nodules stratified by sex. Data shows the number of patients in each group, with percentages in parentheses.

Ultrasound analysis	Female (n=1769)	Male (n=1608)	Total (n=3377)	P value ^a
Goiter	328 (18.5)	420 (26.1)	748 (22.1)	<0.001
Nodules	341 (19.2)	247 (15.4)	588 (17.4)	0.002
Solitary nodule	142 (8.0)	90 (5.6)	232 (6.9)	0.002
Two or more nodules	199 (11.2)	157 (9.8)	356 (10.5)	NS

^aFemale vs men (Fisher's exact test).

additional epidemiological data on the undiagnosed thyroid disorders, confirming the magnitude of thyroid dysfunction in this area.

The large number of patients with abnormal thyroid parameters and/or thyroid nodules, coupled with the well-established gradual progression of thyroid dysfunction, indicates the potential benefit from testing for abnormal thyroid function, at least in these geographic areas.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.
