Abstract

Aim: Adverse outcomes in adult congenital adrenal hyperplasia (CAH) patients are frequent. The determinants of them have not yet been established.

Objective: To establish the prevalence of adverse outcomes and to find determining factors for each of them.

Design, patients, and methods: Cross-sectional monocentric study of 104 patients with childhood onset of CAH (71 women, 33 men). Analysis established first the determinants of clinical, hormonal, genetic variables and second a composite criterion for some of the outcomes and determinants.

Results: BMI was above 25 kg/m² in 44% of the cohort, adrenal hyperplasia and/or nodules were present in 45% of the patients, and irregular menstrual cycles and hyperandrogenism were found in 50 and 35% of the women respectively. In univariate analysis, the determinants of these outcomes were all linked to disease control, especially 17-hydroxyprogesterone (17OHP) and androstenedione concentrations. Low weight was a determinant of abnormal bone mineral density (BMD) (60% of the cohort). Multivariate analysis confirmed these data. A classic form (CF) of CAH was a determinant of testicular adrenal rest tumors (TARTs) (36% of the men). Total cumulative glucocorticoid dose was a determinant of BMI and TART, whereas fludrocortisone dose was a determinant of TART (P=0.03). In men, the composite criterion was associated with androstenedione concentration and CF. In women, the composite criterion was associated with total testosterone concentration.

Conclusion: The present study confirms the high prevalence of adverse outcomes in CAH patients. These are, most often, related to disease control. The impaired health status of adults with CAH could therefore be improved through the modification of treatment.
Introduction

Twenty-one-hydroxylase deficiency (21OHD) is the most common form of congenital adrenal hyperplasia (CAH) (1, 2). CAH is classified according to symptoms, age of presentation, and genetics, and it is usually divided into two forms: classic, or severe, form (CF) and non-classic form (NCF). Improvement of CAH diagnosis and treatment in childhood has raised the question of adult health and care. Replacing steroid deficiency and avoiding the long-term consequences of CAH and glucocorticoid use are the aims of the current medical treatment. Studies have shown the presence of adverse outcomes in adult CAH patients (3, 4). In a prospective cross-sectional study conducted in the United Kingdom in 203 patients, BMI was found to be higher than that in the health survey for England data, and osteopenia (40%) and osteoporosis (7%) were common (5). In an American cross-sectional study in 244 CAH patients (183 CF, 61 NCF) who were included in a natural history study by the National Institutes of Health, obesity was present in approximately one-third of patients across phenotypes, and 37% of adults had low bone mineral density (BMD) (6). Hirsutism was common (32% CF, 59% NCF). Testicular adrenal rest tumors (TARTs) were found in CF males (33% of boys, 44% of men). Adrenal morphology has not been precisely studied, but some data suggest that CAH patients exhibit an increased incidence of adrenal hyperplasia and tumors (7, 8, 9, 10).

Taken together, these studies suggest that adult patients with CAH have a higher morbidity than that of the general population. However, these complications do not concern all adult CAH patients. Roles for glucocorticoid treatment and the severity of the genotype have been proposed. Recently, Krone et al. (11) analyzed the correlation between the genotype and treatment and health status in 153 adult patients. They found no associations between genotype and clinical parameters in this genotype/phenotype analysis. Nevertheless, the determining factors of the adverse outcomes have never been studied and should be elucidated in order to prevent their onset. In this context, the aims of the present study were to describe the adverse outcomes in a large monocentric cohort of adult CAH patients and to find the determinants of each of them. To perform the study, two different analyses were constructed: the first analysis involved a search for the determinants of each health status criterion (namely, BMI of >25 kg/m², BMD, CT scan for both sexes, the presence of TARTs for men and regular menstrual cycles and hyperandrogenism for women) among genotype, clinical history, and treatment of the disease; the second analysis synthesized the correlated health status criteria in one composite criterion for each sex and assessed the determinants of that criterion.

Subjects and methods

General procedures

We conducted a cross-sectional monocentric study among all of the consecutive CAH patients followed-up in our referral center between January 2003 and June 2013. Diagnosis was confirmed by genetic analysis in all of the patients. Inclusion criteria were: adulthood (>16 years old); the presence of CF or NCF CAH diagnosed during childhood (<10 years old) according to the predicted severity of the mutations; and the availability of complete patient files, including clinical examination, BMD measurements, CT scan, testicular ultrasonography for men, and biological and hormonal evaluation, all of which must have been performed within a 1-month period.

The health status of adult CAH patients was defined by the following criteria. BMI was calculated as weight/height² (kg/m²), and patients were divided into two categories: normal weight of ≤25 kg/m² or overweight/obese. BMD was measured at the lumbar and femoral levels, and patients were divided into two categories: normal or osteopenia/osteoporosis, according to the WHO criteria (12). Adrenal morphology on CT scan was divided into two categories: normal or the presence of adrenal hyperplasia (defined by an arm thickness of more than 5 mm) (13) or adenomas. In women, the regularity of menses was evaluated before the beginning of any therapy known to interfere with the menstrual cycle and was divided into two categories: regular (28±2 days) or oligomenorrhea/amenorrhea. Finally, clinical hyperandrogenism was defined by the presence of hirsutism (a score of >8 in the modified Ferriman Gallwey scale) (14), acne, and/or alopecia; in men, TARTs were detected by testicular ultrasonography.

To determine the total cumulative doses (TCDs) of glucocorticoid and mineralocorticoid, all daily treatment and annual heights and weights were noted for each patient from day 1 of the diagnosis to the day of clinical, hormonal, and anatomical evaluation based on both pediatric and adult files, as previously described (15). Doses of the various glucocorticoids were converted to growth-retarding cortisol equivalents (1 mg of dexamethasone=16 mg of prednisone=80 mg of hydrocortisone)
Each year, we summed every daily dose of treatment and divided the total by the corresponding body area to obtain the annual cumulative doses of hydrocortisone (mg/m² per year). Each patient’s TCD (mg/m²) was obtained by adding together these annual cumulative doses. Average daily hydrocortisone treatments (mg/m² per day) were determined every year.

Blood samples for the measurement of insulin, glucose, total cholesterol, triglycerides, HDL and LDL cholesterol concentrations, plasma 17-hydroxyprogesterone (17OHP), total testosterone, androstenedione, progesterone, estradiol, estrone, adrenocorticotropic (ACTH), and renin were taken at 0800 h after an overnight fast. Steroid medications were taken before the blood tests.

Search for the determinants of the different health status criteria

The first analysis involved an assessment of the relationships between each health status criterion and clinical variables: age at diagnosis; age at start of puberty (Tanner stage G2); clinical form of CAH (CF or NCF); time since CAH diagnosis (years); Prader stage and age at menarche in women; weight, height, waist, and hip circumference; daily dose of hydrocortisone and fludrocortisone; genetic form of CAH (group 0, null mutation; group A, homozygous for IVS2 splice mutation or compound heterozygous for IVS2 and null mutations; group B, homozygous or compound heterozygous for I172N mutation or similar severity; group C, homozygous or compound heterozygous for a non-severe mutation, mainly V281L or P30L); and the biological variables estradiol, follicle-stimulating hormone (FSH), luteinizing hormone (LH), total testosterone, sex hormone-binding globulin (SHBG), 17OHP, progesterone, renin, ACTH, androstenedione, insulin, glycemia, and homeostatic model assessment (HOMA) index.

We sought to synthesize the health status criteria in one composite criterion. The second analysis therefore synthesized the correlated criteria into one composite criterion. A composite criterion was determined for each sex from the phi coefficients. The determinants of each composite criterion were then assessed.

Assays

Serum and plasma samples were stored at −20 °C until analysis. Serum FSH, LH, estradiol, progesterone, total testosterone, SHBG, and dehydroepiandrosterone sulfate were measured by the Modular E170 automated chemiluminescent immunometric method (Roche Diagnostics) with an intra-assay coefficient of variation (CV) of <3.3%. Serum androstenedione was measured after extraction by RIA IM0674 (Immunotec, Marseille, France) with an intra-assay CV of <7.1%. Commercial immunoassays were used to measure 17OHP (OHP-CT, Cis Bio International, Gif sur Yvette, France), renin (Radioimmunométrie renin Cisbio, Cis Bio International), and ACTH (immunoradiometric assay, Immunotech Beckmann Coulter). Insulin was measured by an immunoradiometric assay according to the manufacturer’s protocol (Bi Insulin IRMA, Cis Bio International, Marseille, France).

BMD assessment

Femoral neck and lumbar spine BMD were assessed by a Hologic Densitometer QDR 1000 (Hologic, Roissy, France). BMD results at the femoral neck and lumbar spine L2–L4 were evaluated and expressed as absolute values in g/cm² and T-scores ((BMD—peak bone mass)/S.D.). OFELY Caucasian reference curves were used to calculate the T-scores for the women (18), and Hologic’s TK91 norms were applied for the men. We were able to use T-scores to interpret and compare the results because all of the patients were <40 years old, and the general population’s peak bone mass does not decrease at this age (18). According to the World Health Organization criteria, osteoporosis was defined as a T-score of ≤−2.5 S.D., and osteopenia was defined as a T-score between −2.5 and −1 S.D. Normal bones had a BMD T-score of −1 S.D. or higher (12).

Testicular sonography

Grayscale and color Doppler ultrasonography were obtained in the longitudinal and transverse planes by using an anterior approach. All ultrasonographic examinations were performed by a staff radiologist with experience in scrotal ultrasound.

Adrenal CT scan

Patients underwent computed tomography imaging of the adrenal glands. The size of the adrenal glands was evaluated, and the glands were classified as normal or hyperplasia (arm thickness of more than 5 mm). If adrenal nodules were present, their sizes were measured, and attenuation measurements were obtained.

Statistical analysis

Descriptive statistics used numbers and percentages for qualitative variables and means ± S.D. for quantitative
ones. For the first analysis, the same statistical method was used for each health status criterion. First, a univariate analysis was performed using $\chi^2$ or Fisher’s exact tests for qualitative variables and two-sample Wilcoxon’s tests for quantitative ones. In the second step, a stepwise logistic regression was performed. Potential covariates included in the regression were the ones that were found to be significant with a $P$ value of $<0.10$ in the univariate analysis, and the covariates retained in the final model were found to be significant with a $P$ value $<0.05$ by the Wald test. The second analysis involved two quantitative composite criteria, and it was divided into a composite criterion definition step, followed by a univariate analysis and a multivariate analysis. The composite criteria were determined from the associations between simple criteria, as measured by phi coefficients (phi coefficients are a measure of the association between qualitative variables, and they are numerically equal to Pearson correlation coefficients when the qualitative variables are coded as 0 or 1). Finally, the criteria were defined as the number of coefficients when the qualitative variables are coded as 0 or 1). The univariate analysis was performed using $\chi^2$ and Fisher’s exact tests for qualitative variables and Spearman’s rank correlation coefficient tests for quantitative variables. The multivariate analysis used a stepwise multiple linear regression. Covariates that were linked to the criteria with a univariate $P$ value of $<0.10$ were entered into the stepwise regression, and covariates with a $P$ value of $<0.05$ were retained in the final models. All tests were two-sided, and a $P$ value of $<0.05$ was considered significant. Computations were performed using SAS V9 statistical package (SAS Institute, Cary, NC, USA).

Results

Population

One hundred four patients fulfilled the inclusion criteria, including 71 women and 33 men. The mean age was 27.9 years (range 16–52) at the time of the inclusion. Fifty-three (30 females, 23 males) had the salt wasting (SW) form of CAH. Seventeen patients (15 females, two males) were diagnosed as classical simple virilizing (SV) patients. In the remaining 34 patients (26 females, eight males), NCF CAH was diagnosed during childhood, between the ages of 1 and 10 years, because of premature adrenarche. The mean time since diagnosis was 25 years (range 9–52). Ninety-four patients were on hydrocortisone, ten patients were on dexamethasone, and none were on prednisone. The age at diagnosis and evaluation and the glucocorticoid doses for the males and females in each subgroup (CF and NCF) are presented in Table 1.

The prevalence of CAH adverse outcomes for each sex are represented in Fig. 1. In summary, BMI was $>25\text{ kg/m}^2$ in 44% of the patients (53% of women, 40% of men; mean BMI 24.9 kg/m$^2$, range 17.9–45.6). Eighty-seven patients underwent BMD assessment. BMD was found to be abnormal in 60% of them (50% of women, 79% of men). Seventy-six patients had an adrenal CT scan. Adrenal hyperplasia was found in 45% of the patients, and adrenal adenomas were found in 25% of them. Among the 71 women, 50% had irregular menstrual cycles, and 35% had hyperandrogenism. TARTs were found by testicular ultrasonography in 36% of the 33 men.

Univariate analysis

The determinants of the health status criteria BMI, CT scan, and BMD are presented in Table 2. The determinants of higher BMI were the time since diagnosis and renin, androstenedione, 17OHP, and LH concentrations. The determinants of abnormal BMD were weight (67±11 vs 62±13 kg, $P=0.02$). The determinants of abnormal CT scan were renin, androstenedione, ACTH, 17OHP, and progesterone concentrations. In women, the presence of hyperandrogenism or irregular menstrual cycles was also related to the hormonal control of CAH, including 17OHP, androstenedione, or ACTH concentrations.

CAH, congenital adrenal hyperplasia; TCD, total cumulative dose. $^*P<0.05$, $^aP<0.01$, $^bP<0.001$ non-classic vs classic form in each sex. $^{15}P<0.05$ men vs women in each form of CAH.
calculated TCD, we identified that 26 patients had received dexamethasone during their lifetime. TCD of glucocorticoid was $201 \pm 92 \text{ g/m}^2$ in patients with CF CAH and $62 \pm 51 \text{ g/m}^2$ in patients with NCF CAH. TCD of fludrocortisone was $23 \pm 40 \text{ mg/m}^2$ in patients with CF CAH and $0.4 \pm 1 \text{ mg/m}^2$ in patients with NCF CAH. TCD of glucocorticoid before 18 years was calculated to represent pediatric doses of HC. Pediatric TCD dose was $123 \pm 57 \text{ g/m}^2$ in patients with CF CAH and $47 \pm 17 \text{ g/m}^2$ in patients with NCF CAH.

TCD of glucocorticoid was a determinant of BMI ($137 \pm 97$ for patients with normal BMI vs $199 \pm 103 \text{ g/m}^2$ for patients with BMI of $>25 \text{ kg/m}^2$, $P=0.01$) and TART ($125.9 \pm 105.5 \text{ g/m}^2$ for patients without TART and $199.3 \pm 95.6 \text{ g/m}^2$ for patients with TART, $P=0.05$). Pediatric TCD dose was a determinant of BMI ($74 \pm 49$ for patients with normal BMI vs $128 \pm 79 \text{ g/m}^2$ for patients with BMI of $>25 \text{ kg/m}^2$, $P=0.02$), abnormal adrenal CT scan ($88.7 \pm 54.8 \text{ g/m}^2$ for patients with normal CT scan vs $120.5 \pm 61.0 \text{ g/m}^2$ for patients with abnormal CT scan, $P=0.03$). TCD of fludrocortisone was found to be a determinant of the presence of TARTs ($8 \pm 14 \text{ mg/m}^2$ for patients without TART and $30 \pm 52 \text{ mg/m}^2$ for patients with TART, $P=0.03$).

**Multivariate analysis**

Multivariate analysis was performed in the whole population for BMI, BMD, and CT scan. The determinants of BMI of $>25 \text{ kg/m}^2$ were age (odds ratio (OR) = 1.074 (1.013–1.139), $P=0.01$) and androstenedione concentration (OR = 1.152 (1.051–1.262), $P<0.001$). Concerning

NA, not appropriate; NS, nonsignificant.

BMI was divided into two categories: normal weight ≤ 25 kg/m² or overweight/obese.

BMD was divided into two categories according to the WHO criteria: normal or osteopenia/osteoporosis.

CT scan was divided into two categories: normal or presence of adrenal hyperplasia (defined by an arm thickness of more than 5 mm) or adenomas.
the presence of abnormal BMD, the only significant determining factor was weight (OR=0.966 (0.932–1.001), P=0.05), and for abnormal adrenal CT scan, the only determining factor was androstenedione concentration (OR=1.142 (1.048–1.245), P=0.002). In women, a determinant of irregular menstrual cycles was 17OHP concentration (OR=1.014 (1.003–1.026), P=0.01), and for the presence of hyperandrogenism, the determinants were 17OHP (OR=1.022 (1.005–1.039), P=0.01) and estradiol concentrations (OR=0.951 (0.915–0.988), P=0.01). Multivariate analysis could not be performed in men because of the low sample size.

**Composite criteria**

All criteria were positively correlated, apart from the BMD measurement, which was negatively correlated with the others. We therefore synthesized all of correlated criteria into one composite criterion. A composite criterion was determined for each sex from the phi coefficients (data not shown). Thus, the composite criterion was defined as the total number of the following positively correlated events: in men: BMI of >25 kg/m², the presence of TARTs, and the presence of an abnormal adrenal CT scan; in women: BMI of >25 kg/m², the presence of irregular menstrual cycles, and hyperandrogenism.

Twenty-six men were included in the analysis. The factors that were positively correlated with the composite criterion were cumulative hydrocortisone dose per surface (r=0.39, P=0.0375), age at puberty (r=−0.65, P=0.004), androstenedione (r=0.52, P=0.0064), androstenedione (r=0.51, P=0.0073), and 17OHP concentrations (r=0.47, P=0.0153). Clinical form was close but not statistically significant (CF 0.5±0.8 vs NCF 1.7±1.2, P=0.06).

The independent factors found by multiple regression analysis were androstenedione concentration (partial r²=0.18, P=0.0276) and clinical form of CAH (CF vs NCF, partial r²=0.1579, P=0.0392).

Fifty women were included in the analysis. The quantitative factors that were positively correlated with the composite criterion were age at puberty (r=−0.47, P=0.0115), androstenedione (r=0.50, P=0.0004), renin (r=0.38, P=0.0098), 17OHP (r=0.52, P=0.0001), testosterone (r=0.50, P=0.0002), and progesterone concentrations (r=0.48, P=0.0011). No qualitative factors were associated with the composite criterion. Using multiple linear regression analysis, only one factor was found to be significant: total testosterone concentrations (r²=0.28, P=0.0004). Similar results were obtained when considering only patients with CF CAH.

**Figure 2**

Annual average daily hydrocortisone equivalent doses from birth to 25 years old.
The present study was designed to highlight the determinants of adverse events in a single cohort of adult patients with childhood onset of CAH. Overweight and obesity were frequently observed (44%), as were abnormal BMD (60%), irregular menstrual cycles (50%), hirsutism (35%), and TARTs (36%). These results are in accordance with previous results from other adult cohorts (5, 6). We were also interested in adrenal morphology, which had not been studied previously, and we found that adrenal hyperplasia and/or nodules were frequent (45%). We identified determining factors for all of these health outcomes.

The prevalence of obesity and overweight in the present CAH patients is similar to that found in the latest nationwide survey (19). Obesity is estimated to be found in 15% of the French adult population: 15.7% of adult women and 14.3% of adult men. Overweight is estimated to be found in 32% (26.3% of women, 38.8% of men). In the present study, obesity was present in 15% of the patients and overweight in 29%. The determinants of overweight and obesity in the present CAH patients were age and hormonal control of the disease, that is, patients with the highest BMI had less hormonal control, based on renin, androstenedione, and 17OHP concentrations. TCD was also found to be a determining factor of high BMI, especially pediatric TCD. It should be noted that our patients were most likely treated with higher steroid doses during early life than the amounts that are recommended nowadays. It has been previously demonstrated that early rebound of BMI is associated with obesity in late childhood (19). This has been shown to be linked with hydrocortisone dosage and parental BMI (20). These findings reinforce the need to carefully monitor these patients from childhood, seeing as increased BMI in adults has been associated with increased fat mass and the presence of abdominal obesity, which represent important predictive factors of cardiovascular disease (4, 20, 21, 22, 23, 24, 25, 26, 27).

We confirmed the results from our previous study on the high prevalence of BMD alteration in this population, especially in men (4, 15). We did not have a control population, but we used OFELY Caucasian reference curves to calculate women T-scores (18), and Hologic’s TK91 norms were applied for men. In fact, 60% of the participants had bone demineralization according to the WHO criteria, which is superior to a Gaussian repartition, in which 16% of the general population is under –1 S.D. (15). We recently conducted a trial to establish the role of the glucocorticoid TCD on BMD (15). We established that there was a negative relationship between TCD and lumbar and femoral BMD. BMI also appeared to protect patients from bone loss. In the present study, increased weight was a protective factor for osteoporosis and osteopenia, but we were not able to find any association with TCDs of glucocorticoid, probably because of the large cohort studied.

In women, the present study showed the importance of hormonal control on the regularity of menstrual cycles and confirmed that CAH women do not necessarily present a disruption of the gonadotropic axis and anovulation as a result of early exposure to adrenal steroids, as we had previously shown (28). This is also in accordance with a study by Castera’s et al. (29) which showed low fecundity in classic CAH patients but normal fertility in patients with parental project and spontaneous pregnancy in patients with strict control of progesterone concentrations in the follicular phase of the menstrual cycle. In men, TARTs were the only event that could not be linked to hormonal control, but they were associated with the severity of the disease (30, 31, 32). Indeed, TARTs were found only in patients with CF CAH. Nevertheless, a recent study highlighted the presence of TARTs in two patients with NCF CAH (33). This should be confirmed in the future by other groups, because none of our eight males with NCF exhibited TARTs. We also showed that total glucocorticoid dose of hydrocortisone and fludrocortisone were determinants of TARTs. It has been shown that TARTs express adrenal-specific enzymes and ACTH.

Health outcomes in CAH patients

A Bachelot and others

Clinical Study

and angiotensin II receptors (34). This could be an expression of a more severe form of CAH or non-compliance (i.e., less compliant patients received higher doses of glucocorticoid but nonetheless retained poor disease control and developed TARTs), or it could suggest that the doses of glucocorticoid were adjusted according to the presence or absence of TARTs. We cannot exclude any of these hypotheses on the sole basis of the present results.

Few studies that evaluated adrenal morphology by CT scan exist in CAH patients (7, 8, 9, 10). One such study showed that among 26 patients (eight with the NCF, four with the SW, and 14 with the SV form), nodules were found in six of the 11 patients with poor hormonal control but not in the 15 patients with regular or good hormonal control. Adrenal nodules in these six patients demonstrated a considerable size reduction and even disappearance after adequate replacement therapy, which suggests that these nodules were ACTH-dependent (10). Another study reported a high incidence of adrenal masses, which were present in 82% of the patients (7). The present study in a larger cohort of adult patients confirms the high incidence of adrenal hyperplasia and/or nodules and clearly shows their hormonal dependence, because the determining factors of these anomalies were all linked to hormonal control (i.e., high ACTH concentrations).

Pediatric TCD was found to be a determinant for abnormal CT scan, which highlights the importance of precocious good hormonal control for preventing adrenal hyperplasia development and subsequent difficulty with hormonal equilibration.

In the present study, we thus demonstrated that all of the undesirable outcomes observed in adult CAH patients, except for TARTs, were linked to disease control. In particular, hormonal parameters that are linked to disease control, especially 17OHP and androstenedione, were found to be determinants of these outcomes: their concentrations were found to be higher in patients with worse outcomes. Moreover, when using the composite criterion, which affects the health outcomes of the CAH patients, we showed that it too was linked to hormonal parameters: that is, patients with the worst hormonal control have the worst health outcome. Consequently, we identified a subgroup of patients who poorly responded to treatment in terms of disease control but still developed an adverse effect, such as obesity or osteoporosis. Recent studies conducted by Han et al. (35, 36) showed similar findings to those in the present study: they examined the impact of glucocorticoid treatment regimens on health outcomes. Their results suggest that increased glucocorticoid dose is associated with increased blood pressure but does not necessarily improve disease control. A possible explanation developed by that group was that the less compliant patients received higher doses of glucocorticoid but nonetheless retained poor disease control and had worse metabolic profiles as a consequence of intermittent high glucocorticoid doses. This should be evaluated further and more precisely. Another explanation could be the presence in some patients of particular glucocorticoid receptor polymorphisms, which have been shown to be associated with poor metabolic state in CAH patients (37). Another interesting finding is the demonstration that clinical form of CAH (CF vs NCF diagnosed in childhood) does not seem to be a determining factor of adverse outcomes if the patients have controlled disease. Overall, the present study and the CaHASE cohort study suggest that poor health outcomes in adults are closely related to their treatment rather than to the severity of the enzyme deficiency (34, 35). The long-term impact of these complications on bone, cardiovascular events, and mortality should be analyzed in a longitudinal way in this population. Indeed, a recent study showed an increased mortality in patients with CAH, especially CAH resulting from adrenal crisis (38).

The present study has two major biases: first, missing data may be a limitation, seeing as not all of the patients had extensive data recording. The study of this cohort nevertheless took advantage of the monocentric design. Despite this bias, our cohort was large enough to give power to our results, especially in women. The reduced number of men was also observed in other cohorts (6, 11, 34, 35). The other bias is the genetic heterogeneity of the population. However, we found the same results when excluding NCF patients. Moreover, time since diagnosis was a determinant of some criteria in univariate analysis, but this association did not persist in multivariate analysis. These results are not applicable to NCF cases diagnosed in adulthood, which are treated beginning at a later age and are not systematically treated with glucocorticoids.

In conclusion, the present study confirms the high prevalence of adverse outcomes in adult CAH patients but especially underlines for the first time specific determinants of those outcomes, that is, the predominant role of hormonal control and treatment in the development of these outcomes in a large monocentric cohort. The evidence that subgroups of patients poorly responded to treatment in terms of disease control but still developed some adverse effects should be further studied. Poor hormonal control and adverse outcomes are common in CAH, which necessitates new treatments. Osteoporosis and obesity prophylaxis and TART screening should begin
during childhood. A longitudinal study is needed to precisely identify the natural history of these adverse outcomes and to confirm their risk factors. Controlled drug trials in adults with CAH should also be carried out in order to define the best therapeutic approaches in these patients.

Declaration of interest
The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.

Funding
This work was supported by a grant from Association Surrénales.

Author contribution statement
A Bachelot designed the study, analyzed the data, and wrote parts of the manuscript. J L Golmard analyzed the data and performed all of the statistical analyses. J Dulon and N Dhammoun managed the database. M Leblan performed the hormonal assessment. C Bouvattier, S Cabrol, J Leger, and M Polak included their patients and reviewed the manuscript. P Touraine designed the study and reviewed the manuscript.

Acknowledgements
We thank Dr Catherine Cormier for helpful discussion.
